THE JOURNAL

OF THE

American Medical Association.

///

CONTAINING

THE OFFICIAL RECORD OF ITS PROCEEDINGS,

AND THE

Reports and Papers Presented in the Several Sections.

EDITED FOR THE ASSOCIATION BY N. S. DAVIS, M.D., LL.D.

VOLUME III.

1884.

408717
11.1.43

CHICAGO:

PRINTED FOR THE ASSOCIATION BY THE REVIEW PRINTING AND PUBLISHING CO.

79 AND 81 WABASH AVENUE.

“ The American Medical Association, though formally accepting and publishing the reports of the various Standing Committees (and Sections), holds itself wholly irresponsible for the opinions, theories, or criticisms therein contained, except otherwise decided by special resolution.”—TRANSACTIONS, 1851.

Journal of the American Medical Association.

EDITED FOR THE ASSOCIATION BY N. S. DAVIS.

PUBLISHED WEEKLY.

VOL. III.

CHICAGO, JULY 5, 1884.

NO. 1.

ORIGINAL ARTICLES.

ADDRESS IN STATE MEDICINE.

BY DEERING J. ROBERTS, M.D., OF NASHVILLE, TENN.,
CHAIRMAN OF THE SECTION ON STATE MEDICINE.

Read to the American Medical Association, May, 1884.

MR. PRESIDENT AND GENTLEMEN OF THE ASSOCIATION:

The Section of State Medicine, as many of you are doubtless aware, was established and thoroughly organized at the twenty-fifth annual meeting of the Association, at Detroit, in 1874, and has been presided over by some of the ablest, most learned, and illustrious members of this Association. In accepting the chairmanship one year ago, it was with no inconsiderable degree of apprehension and doubt as to my ability to properly discharge one of the duties of the position, and to place before you an address worthy the attention of those who have listened with pleasure and benefit to such men as Bowditch, of Boston; Kedzie, of Michigan; Cabell, of Virginia; Hunt, of New Jersey; and others whose names have been heralded far and wide, at home and abroad, as active, earnest, and able workers in this most important department of medical science.

The work of this Section since its organization, as well as that in its particular line in the earlier years of the Association, whether embraced in the reports of the various committees on Epidemic Diseases, or the individual papers and essays in the special province of State Medicine, forms a most important part of the published Transactions in each year of the Association's existence, and has accomplished fully as much as other even more popular Sections, towards adding to the glory of the Association, its prestige and its reputation; towards giving "frequent, united, and emphatic expression to the views and aims of the medical profession," or "cultivating and advancing medical knowledge; elevating the standard of medical education; promoting the usefulness, honor, and interests of the medical profession; enlightening and directing public opinion; exciting and encouraging emulation and concert of action in the profession; and facilitating and fostering friendly intercourse between those who are engaged in it." Careful examination of the 33 volumes of Transactions, and the now complete first volume of the Asso-

ciation JOURNAL, will reveal a vast amount of valuable labor, rich in fruitage, teeming with evidences of successful progress—an intellectual mine, in which is treasured up the matured experience, the scrutinizing thought, and earnest work in this important department.

Accepting the graphic, yet concise definition of Dr. Stanford E. Chaillé, of New Orleans, than which we can get no better if we would, and would not if we could: "*State medicine is the application by the State of medical knowledge to the common weal; and embraces every subject for the comprehension of which medical knowledge, and for the execution of which State authority, are indispensable,*" we shall not undertake to tax your patience with a repetition of the gradual, yet positive progress made therein. Suffice it to say, that while there have been no discoveries or advances of a meteoric brilliancy in the past twelve months, yet there has been progress. Some old things have been unlearned—which is sometimes no less important than that some new ones should have been learned.

While new discoveries and new developments in State medicine are of such importance and value, we can patiently wait several successive years in expectation of some one finding a Koh-i-noor, and profitably spend our time and skill in polishing up, and putting into practical use the rich discoveries of the past. The germ factor of cholera—distinctly stated more than thirty years ago by a Tennessee doctor,¹ as well as the germ theory of fevers by another Tennessee doctor,² a little later, has been burnished, polished and crystallized by later observers into cognate facts: and to these have been added by more recent investigators a like cause for tuberculosis, as well as other diseases. Granted that these ætiological studies are of greatest importance to the individual physician in his essays at individual prophylaxis, yet how much more important in State and national work!

The studies in regard to sewage and drainage; the purities and impurities of the air we breathe, the water we drink, and the food we eat; contagion, infection, hereditary, zymotic or other influences are being prosecuted day by day with a vigor and earnestness and an enthusiasm that will surely result in progress. It may be slow, but it will be none the less sure.

Is it necessary that I should inform you that Asiatic cholera again began its accustomed westward march from its lair in the Ganges, in the far distant East;

¹W. D. Dorris, M.D., *Nashville Journal of Medicine and Surgery*, Vol. I, No. 3, June, 1851, p. 154.
²Thompson on Fevers, 1859.

that it advanced its skirmish line even to Western Europe, with heavy battalions doing their murderous work 'neath the shadow of the Pyramids? But, "Thus far shalt thou go, and no farther," was the edict of State medicine in the good year 1883.

Yellow fever had even fastened its fangs on our Southern border, but by the strong arm of State medicine was it held at bay. Although small-pox has been claiming a victim here and there at long and distant intervals, in gratifying contrast to its former holocausts, yet even the few and infrequent sacrifices it has claimed were the result of neglect of the dictates and teachings of State medicine.

But enough of this. That familiarity with the scientific literature of the day which is incumbent on every member of this representative scientific organization, or a cursory walk through the Museum of Hygiene of the Navy Department here at hand and an examination of its records, will give you a better idea of the recent developments pertaining directly to State medicine, and will be decidedly more entertaining than any that I can lay before you. Therefore I may be pardoned if, following the line of some of my predecessors, I omit a citation of the "advances and discoveries of the past year" in this particular Section, more especially as there are one or two questions to which I desire to call especial attention. In doing so I must ask your indulgence if the views advanced, perchance, may seem to all or some of my audience to transcend the pale of orthodoxy. Yet I can sincerely claim honesty of purpose, and will yield to none in sincere and earnest desire to do good to my fellow-man, and will invoke a calm, dispassionate and impartial consideration of questions fraught with greatest importance to ourselves as physicians and as men, as well as to our fellow-men.

A cursory review of the published transactions of this Association, beginning with the Convention that gave it origin in 1846, down to the present day, will convince the most casual reader of the importance of the subject of medical education. Time and again does it show up in our printed minutes and published papers and essays. The effort all along the line has been to bring the aid of legislative enactments to bear upon it.

Am I heterodox when I say that it is not a subject for the State or national law-maker? Is State authority "*indispensable*" for its elevation? Is there need of legislative interference in behalf of medical education? The conditions under which men shall be allowed to practice medicine, the amount and kind of knowledge which they should be obliged to show, the way in which their possession of that knowledge should be tested, the preliminary education prior to, and the length of time they ought to study, the extent to which the details of that study should be regulated by compulsory rules or left to individual option—these are questions upon which there are wide differences of opinion in this country. In England during nearly the thirty years past, and on the continent of Europe for a longer period, entire governmental control obtains. Here, we have *free medicine*, as well as *free religion* and *freedom of speech*. A few States from time to time have essayed their hands,

and with what result? Over fifty years ago, Daniel Drake, than whom this country never produced a more original mind, a closer reasoner, or one of deeper thought, in an "*Essay on Medical Education*," enunciated the following:

"More than half the States of the Union have laws to regulate the practice of medicine, but I am by no means convinced that they have ever done any real good to the profession or society. New York and Ohio have such laws; Virginia and Kentucky none. It remains to be shown whether the profession in the two former is more respectable than in the latter. I am disposed to believe not."

And to-day what shall we say? Are the people, or the doctors, in a better condition in Illinois than in Indiana? Take Michigan in the Northwest, and Kentucky in the Southwest, and compare their medical men with those in Massachusetts. At Ann Arbor we can see that regular medicine has been *brought down* to a level with one faction of the irregulars, while grand old Harvard holds her head aloft, and the glorious banner of regular medicine floats in its purity, its glory, and a most enviable renown. My own State of Tennessee has furnished in the past an honored and an honorable delegation to your councils. The late A. H. Buchanan, of Tennessee, was one of your first vice-presidents, and two of his colleagues had the honor to occupy subsequently the presidential chair with credit to themselves and this Association. The State from which they hailed has ever left medical matters solely to medical men.

Even in England there are to-day wide differences of opinion on this subject. They are not altogether satisfied that their plan of protection is the better one. Quite a respectable minority hold that they are not benefited by legal control, and that although freedom in medicine is subject to some abuses, it is perhaps the better plan. The medical literature of most benefit to the world is the growth of the present century, and notably the latter half of it. Are not American works being reproduced in the different tongues of Europe? Has it received no aid from this side the Atlantic?

"*Flint on Practice*," or "*Gross or Hamilton on Surgery*," as well as many other volumes of indigenous origin, are as favorably commented on by foreign writers and readers as the most noted productions of the old world.

The *London Medical Times and Gazette* of Nov. 12, 1881, in discussing in a remarkably fair, candid and impartial article the subject of "Medical Education and Registration in America," says that "American medical literature is very voluminous, characterized by great originality, inventive genius, industry and practicality." And again, can we not see that certain departments of our art have been created in this country, and others notably improved? Did it require legislative aid to develop the genius of a Sims or the inventive originality of a Sayre? The discoveries of Jenner and of Harvey occurred when medicine was as free in England as in the day of Morton, of Massachusetts, or Long, of Georgia, when anæsthesia just dawned upon suffering humanity, to say nothing of Dorris and Thompson, of

Tennessee, who were the discoverers of the germ-world, as much as was ever Columbus the discoverer of this continent.

Professor Huxley in an address "On the Intervention of the State in the affairs of the Medical Profession," delivered at the London Hospital Medical College, and published in the *British Medical Journal* of Oct. 13, 1883, is thus reviewed in a very able editorial in the *Chicago Medical Journal and Examiner*:

"Professor Huxley practically presents three questions: 1. Why should the State interfere with medicine and the medical Profession? 2. If there be ground for such intervention, what should be its extent? 3. If such intervention be right and proper, how can it best be carried into effect? The answers which he proposes to these several inquiries, seem to us eminently wise and judicious; and some of the commentaries they suggest, are interesting to us on this side the Atlantic.

With respect to the first question the speaker took the ground that it was not the duty of the State to take medical charge of the public, to protect it against incompetent persons in general, and in particular against quacks and impostors. He thought that it was more wholesome for the public to take charge of itself wherever it can do so in this as well as in other matters, and that on the whole there should be no interference with the liberty of each person to do that which he likes when he does not interfere with others. The actual impossibility [which all reasonable men must admit, and of which we, in the State of Illinois, have seen the most conspicuous and notorious examples] of absolutely prohibiting the practice of medicine by people not specially qualified for it, is freely admitted by Professor Huxley. The old lady who orders a cranberry poultice, the druggist who undertakes to relieve the pain of an aching tooth, or of any other afflicted organ of the body, will enjoy these peculiar pastimes in the face of all legal restrictions. The charlatan will do no less, and always more. "*Facilis decensus est Avern!*" He has smiled equally at the British, Gallic, and Tentonic barriers to bar his progress. Where there is a throne, there will always be a pretender. The shadow will always follow the substance. We shall always have him with us, whether the truth or its counterfeit prevail, is determined not by a national legislature, but by the extent of the diffusion of knowledge among the people whose feeblest index that legislature often is.

Professor Huxley, however, strikes the key-note of the whole question when he points to the death of the individual citizen as the important moment which the State should officially recognize. Here the violation of the individual ceases. In civil and criminal cases, the law should be able to have recourse to persons qualified to give expert evidence. Here lies the justification of the intervention of the State. It says to one class of men: 'Practice medicine, if you like, on any basis, on any theory, whether you are qualified or not qualified;' and to another class: 'Consult whom you choose, pay whom you will for attendance upon you in your illness; but before I can re-

ceive from you a certificate of death, before I can appoint any of you to any civil or military service, the standard of my qualification must be attained. The giver of the certificate, the incumbent of the office, must be those whom I can recognize as fit for such service.' In brief, the State intervenes only at those points where the State touches the individual. With the old woman's elder-flower tea, with the druggist's cough panacea, with the quack's startling announcement of the cure for consumption, the State has no more to do than with the numerous patent religious enterprises of the day in which we live."

This is rather a lengthy quotation. But as enunciated in a review of an address delivered on British soil, in the leading medical journal of the most protected of all protected States of America, we cannot refrain from using it. Yes, when you select your servant, your lawyer, or your preacher, he must rise to the standard of your requirements. So with the State. This right has been delegated to the States. Has the other? With the enlisted men and commissioned officers of the Army and Navy, the State has a distinct contract to provide them with medical attention, and has a right to require a certain standard in that particular as in the bread, the beans, and other supplies furnished them. Certain requirements are exacted in all civil and military appointments, and the appointing power has the right to fix the standard.

Nay, further, the State has the right, and exercises it, of prescribing the very garb of her appointees. And shall not you, or I, array ourselves in cotton or linen in winter, or in furs or heavy woollens in mid-summer, so long as we remain private citizens, attending to our own business, and molesting no one? Granted, that in the one instance a life is sacrificed to pneumonia, or in the other to sun-stroke, has any legislator, State or national, other right than to pity the suicide for his folly? It might justify a writ of "*lunatico de inquirendo*," but alone, would not secure a verdict of lunacy.

The State may prevent fraud in the sale of unwholesome bread or unsound meats—for fraud is criminal; it may prohibit as a nuisance to one or more citizens, the keeping of such articles by one; but if he annoy not his neighbor, can the State prohibit his eating them himself? If he give it to his wife, his child, his servant, or the stranger within his gates, I grant you that he may be chargeable with murder. But eating it himself—is it an offence against the State? Would not public opinion even, readily agree, that the sooner the State is rid of such a one, the better!

I can readily and heartily agree with England's "uncrowned king of science," in protesting against State authority prescribing my pill, my potion, or my plaster,—I might be compelled to submit to infinitesimals.

To take another view of the subject. Can we better ourselves, our profession, or our fellow-man? Take the history of our own great country and compare it with other nations. Will we suffer thereby? In the March number of the *Sanitarian*, I find on pages facing each other, that the death-rate of Toledo, Ohio, was 15.3, while in London, it was 18.8 per

1,000. In 28 of the largest towns of England, with a population of 8,500,000, the death-rate for the third quarter of 1883, averaged 19.9 per 1,000, while in 28 of the largest towns of the United States, with a population of 7,395,000, the death-rate for four weeks ending January 26, 1884, was 19.36. In the *Sanitary Engineer* of March 6, 1884, page 337, the statement is made that the death-rate per 1,000 in 30 of the cities of the United States for the week ending February 23, was 20.3, while in 28 of the large towns of England for the week ending February 2, it was 20.5. We think we can stand the comparison.

Take the Medical and Surgical History of the War of the Rebellion, published by the late Surgeon-General of the United States Army. Will it not bear favorable comparison with any military medical and surgical records of a like period?

We have already cited the field of general medical literature; but we think it will bear repetition. Medical journalism, which in my humble opinion, has done, and will do, far more to elevate the standard of medicine in an educational, as well as a practical point of view, than all State and national legislation, had its very origin on our own goodly soil. Yes, by far, the brightest diadem the coronet of medicine ever bore is "native and to the manner born."

Take the discoveries in medicine, whether in anatomical or physiological facts, therapeutical or prophylactic edicts, the devices of surgery, the suggestions of practice, or the grand innovations of the specialists, from gynæcology to ophthalmology, and is not a fair and honorable proportion ours? These are questions for us to consider, and to consider well, before we throw down our grand and glorious birthright of free medicine—alike honorable and independent.

I can readily see how you can bring medicine down by legislation, but pardon the obscurity of my vision when I say that I can see no way of raising it up by the same means. I can see how legislation can force me to stand on the same plane with those "who claim a special designation and trade upon the same." I can see how honorable, regular medicine can be pulled down to the level of the irregular, the nostrum-vender, and the charlatan. If medicine is to rise, there is ample power within her own domain. If medicine is to be elevated, to medical men alone must be entrusted the lever. If medicine is to be regulated, in this Association we can find the power which but needs to be put into action. In a series of resolutions adopted by this Association in 1869 we find the following preamble:

"WHEREAS, The history of medical legislation in the various States of this Union clearly shows that no reliance can be placed on either the uniformity or the permanency of any laws relating to the practice of medicine—"

In 1872, Dr. David W. Yandell, of Kentucky, in his address as President of the Association, stated that:

"The profession does not appear to my mind 'corrupt and degenerate.' I do not believe 'it is going from bad to worse,' and that the people will

have to rise in their might and stay its downward progress. I cannot see the thing in this light at all, and so am not ready to appeal to Federal Legislation to correct our evils, and certainly should not go to Congress to establish National Medical Schools."

In 1874, at the twenty-fifth meeting of the Association, Dr. J. M. Toner, of this city, as your presiding officer, said:

"The hope entertained by some physicians of excluding irregular and incompetent practitioners from the profession by legislative enactment and penalties is, I apprehend, in our country, not to be realized."

Consulting the published transactions of this Association from 1846 until to-day, will evince to you that this subject has been carefully and well considered; effort after effort has been made, and yet National legislation has not been accomplished. The people through their representatives have said that they did not want it. Shall we not abide by their decision, that State authority is not needed, and thus relieve State medicine from a futile and unnecessary struggle, and free its arms the more successfully to cope and grapple with the many foes to be found in its own proper field?

The next subject to which I wish to call your attention is a more perfect organization for State medicine. And in doing so I do not propose to become the partisan of either faction involved in an unfortunate wrangle in regard to National Sanitary matters. I most cordially recognize and acknowledge the excellent results as accomplished by the National Board of Health, both in its labors of investigation and as the custodian of the appropriation made by Congress for the prevention of epidemic diseases up to July, 1883. The members of that Board as Scientists and as Sanitarians are deserving of the lasting gratitude of the American people. As cheerfully do I accord the same meed of praise to the Marine Hospital Service from July, 1883, to the present day. But I must deplore and sincerely regret the contest that has arisen between them. Having carefully examined into this imbroglio; having impartially considered both sides of the question, and having patiently and carefully read the statements made by the opposing parties, I can only say unfortunate for the National Board of Health, unfortunate for the Marine Hospital Department, and most unfortunate for National Sanitation.

But let us try and correct the error. The National Board of Health is the result of earnest and faithful work on the part of this Association, and its younger ally, the American Public Health Association. It was authorized and established by Congress in answer to repeated applications of the two organizations, so terribly emphasized by the yellow fever epidemic of 1878.

With a morbid dread of an autocracy, with an apprehension of placing too much power in the hands of one man, I am of the opinion that error was committed in its inception. It was made too unwieldy. Incompatible elements, apparently, have entered into its composition, and in the struggle that has ensued we have seen that these representative men have "degenerated into detraction, ridicule and unseemly

personalities which can only result in great injury to the public health service." By its representative organization, by selecting its members partly from four departments of public service, and with seven civilians from as many different States, have we not secured a "divided responsibility" ending "in inefficiency and failure?" Can it be possible that with its brief but brilliant record, the auspicious future presaging its advent, it is so soon a stranded wreck?

Would it not have been better to have modelled it in exact conformity with the Departments of our National Government? Surely the Department of Justice is of no greater importance, is of no more utility or benefit than a Department of Health, if organized and sustained in the same manner and on the same basis. I think it would have been far better if we had demanded, and I do not believe it is yet too late, that a Department of Health be created by Congress, with a Chief, the Secretary of Health, or Medical Director of the United States, a member of the President's Cabinet, nominated by him and confirmed by the Senate as other Cabinet officers, and with equal rank and compensation as other members of the Cabinet, said Chief to organize his Department by the appointment of the necessary assistants, sanitarians, scientists, chemists, physicians, surgeons, clerks and other subordinates, just as is organized the Department of Justice and other Departments. Said Chief to advise with the President when necessary, and to report the working of his Department to Congress as required.

To this Department would be referred all matters of International Sanitation, such as quarantine of seaports; the regulation of inter-state quarantine, and the aid and assistance to be granted State and local sanitary organizations, when occasion required, under certain restrictions. But I have not time or space to go into specific details, and they will readily suggest themselves.

With the advice of this Department, Congress could intelligently legislate as regards all matters of National sanitation, including marine and inland quarantine. With the advice of such a Department Congress could intelligently and successfully aid State and local health boards and officers in their efforts at prevention of diseases requiring more ample means of suppression than within their power.

The objection, and I believe the principal one that can be brought against the National Board of Health, was that it was too unwieldy. That there was an objection, and a tangible one, is evidenced by the fact of its failure to secure that confidence necessary for its proper maintenance, or to hold the position originally assigned it. I have no hesitation in asserting that a similar result would have inevitably ensued if the Department of the Navy, or the Army, the Department of Justice, or the Interior, had been organized on a similar basis—no matter how able, how eminent, or how efficient the members of the Board in charge.

As before stated, a Department of Health is of fully as much importance as that of justice, war, or the navy. Recognition of this fact is but an evidence of progress in civilization. "Public health is public

wealth" is an established axiom in all civilized and intelligent communities at this day. As enunciated by England's great prime, "it should be the statesman's greatest care."

Fully recognizing its needs, as our entire people now do, the question is, how best to meet the issue? Our national legislators are elected by the people, and from the people. They are ever ready to pass any law that will benefit those whom they represent, and while occasionally they may have one in their midst who has had special training in medical or sanitary science, or one who like our distinguished Senator from Tennessee—the Hon. Isham G. Harris—under the pressure of impending circumstances, will turn the entire weight of his intellect, and bring his every nerve and fibre to bear upon questions of National sanitation, yet the outcome so far has been indifferent good.

The bill establishing a National Board of Health, together with the one for the prevention of epidemic diseases has found serious objections in more quarters than one. Hon. Casey Young, of Tennessee, has recently, in a bill introduced, made certain suggestions in regard to this question. So also may be said of Hon. Mr. Pettibone. These suggestions, I apprehend, will not fully cover the ground. They do not sufficiently comprehend the magnitude of the questions at issue, its many intricacies and the numerous conflicting interests to be reconciled.

The army and the navy have their own particular needs. While their medical staff are composed of able, talented, scientific, thoroughly educated and energetic men, and men who have closely studied the questions of sanitation as regards their particular branch of the service, yet this is entirely different in many particulars from National sanitary work. That the Marine Hospital Service—a sub-department of a department—has quite enough to do in its own particular line, is well demonstrated by the fact that only during the winter just past, individuals under its own care and for whom it was organized, have become charges upon the counties of my own State, and thereby have disseminated the seeds of small-pox in more than one locality on the banks of the Tennessee River.

I do not wish to be understood as recommending an "autocratic power to be conferred on any one man, with sole discretion in regard to quarantine," marine or inland, or other matters belonging to State Medicine. By no means. I, as much as any one, believe in certain rights belonging to the people, certain rights by them delegated to the State, and certain rights of the people and by the States delegated to the National Government. There is no autocracy in the Treasury. Yet, without this Department as now organized, how could our National lawmakers as successfully grapple with the intricate and delicate problems of finance? Is the "dollar of our daddies" of more importance than the lives of our fathers, our mothers, our wives, our children, or ourselves? Are monetary questions more difficult of solution than sanitary, that we grant to Congress an able adviser, with able assistants, educated and trained as each separate need demands, for carrying out the

regulations and edicts of that Congress? Are they more important? It is by no means an autocracy that is needed. Let Congress, as the voice of the people, say what steps shall be taken to meet the invasion of foreign or domestic disease, and that it may act advisedly, and that it may have the means of carrying out its dictates—let it have a Department for this special purpose. Recruit this Department from the army, the navy, the Marine Hospital service, or from civil life, from its head to its most humble subordinate; but these recruits, when in its service owe allegiance to it alone. And when necessity occurs, or emergency arises, give such aid as may be needed from other departments of the government, as such need or emergency may demand.

Is there danger that an inefficient or unsuitable man may be placed at its head? No more danger than that our Chief Executive will appoint, and the Senate will confirm an inefficient or unsuitable man as Secretary of State or of the Treasury. He is responsible to the people. His appointee is responsible to him, and through him to the people for the faithful execution of such laws and regulations as the people, through their representatives in Congress assembled, may decree to preserve them from foreign pestilence or domestic disease.

Dr. J. F. Hibberd, of Indiana, as Chairman of the Section in State Medicine, in his annual address in New York, 1880, very justly compliments the National Board of Health in "that some degree of harmony of action was established among the various State and local Boards of Health that were charged with the immediate execution of sanitary regulations." And further says, that "it should be clearly recognized that the National Board does not supersede local sanitary organizations." Recognizing as I do certain rights and duties belonging and pertaining to towns, cities, States, and the inhabitants thereof, I can foresee and confidently expect a far greater degree of harmony as the outcome of a properly organized department, with a responsible head, than with a cumbrous Board. To use the words of one of the most eminent members of the National Board, Dr. Stephen Smith: "Divided responsibility must end in inefficiency and failure." As in many of our States, we have quite a diversity of legal, social, commercial and other regulations as pertaining to the varied questions of political economy in the different States, all working smoothly together as a whole without conflict because harmonized and properly restrained as regards each other by the various departments of the National Government; so, also, there is just as positive a certainty of harmonizing National, State and local questions of health by a similar department.

Dr. C. C. Cox, of this city, in 1871, advocated views somewhat similar to the suggestions I have the honor to submit. And in 1872 a bill was introduced into the U. S. Senate providing for the establishment of a national sanitary bureau, with a chief executive officer; but as advocated by Dr. Cox, subordinate to the Department of the Interior. The duties of the chief, which are specified at length in the bill, were to collect information on sanitary matters and to re-

port on the same from time to time. He having the appointing power to select such additional officers required, as chief clerk, chemists, experts, etc. Dr. Jno. S. Billings in his report on the National Board of Health and Quarantine to this Association in 1880, says that "there was a general feeling among sanitarians that this bill was not opportune, that the circumstances were such that it would lead to purely political appointments, and that the result would be upon the whole prejudicial to the cause of public hygiene. It therefore received little or no cordial support. The American Public Health Association did not recommend its passage, and it was practically pigeon-holed in the Congressional Committee to which it was referred."

A similar idea was suggested in the American Public Health Association in 1873, by a resolution recommending a National Health Department similar to that of Agriculture or the Bureau of Education. The resolution does not say to what department it should be subordinate.

My objection to Dr. Cox's suggestion is, that if either should be subordinate, the Department of the Interior might be made as an annex to the Department of Health. For of the two, I cannot but think that our National Health, and the questions pertaining thereto, are paramount. As for the political bias that seemed to be so much dreaded, it has no fears for me. If a department is created as suggested, we can, I think, very safely trust the chief magistrate elected by the American people, no matter from what particular political field he may come, to select a head for that department, to manage it according to the regulations of a Congress elected by the same people.

ON THE IMMEDIATE AND REMOTE EFFECTS OF EMMET'S OPERATION.

BY JOSEPH TABER JOHNSON, A.M., M.D., WASHINGTON, D. C.

(Presented to the Section on Obstetrics and Gynecology, American Medical Association, May, 1884.)

MR. CHAIRMAN AND GENTLEMEN:

The title of this paper indicates the desire of its writer to draw attention to some of the immediate and remote effects of trachelorrhaphy. There is so little to be found in our gynecological literature upon these subjects, it occurred to me that a collection of the combined experiences of a number of our prominent gynecologists might possess much interest as well as value, and aid somewhat in the settlement of some of the points in regard to the effects of this operation, which have been raised abroad and at home within the past few years.

Perhaps I may be pardoned for a digression, a moment, in reference to the name of this operation. Emmet, its justly celebrated author, described it as an operation for the restoration of a lacerated cervix

uteri, in his first paper, read before the Medical Society of the County of New York, in February, 1869. In his second paper, read before the same Society in September, 1874, he retains the same name.

Dr. E. C. Dudley, of Chicago, was the first to give it the name of trachelorrhaphy (New York *Medical Journal*, January, 1878).

Dr. Paul F. Mundé (*American Journal Obstetrics*, January, 1879), in his excellent article on the indications for the operation, in his desire to be more exact and explicit, named it hysterio-trachelorrhaphy. Dr. Emmet remarks (see second edition of his work, p. 450): "It would be but human nature for the uninitiated to dread the severity of an operation so termed, and I should prefer to use the English expression." The editor of the *Medical News* calls it tracheloplasty in a recent editorial.

I wish to propose that we should, in simple justice to its great originator, speak and write of this operation—which Thomas, Marion Sims, Fordyce Barker, Goodell, Howard, Jenks and others have spoken of as one of the most important contributions which have been made to gynecology (within a quarter of a century, Thomas)—as *Emmet's operation*. There are many examples familiar to us all where less valuable contributions to medicine or surgery have been subsequently known by the distinguished name first to describe, propose, or perform it. Thus we have Graves' disease, Basedow's disease, Bright's disease; we also have Syme's operation, Chopart's operation, Sympton's and Sims' operation, on the cervix; and more recently Bigelow's operation, Battey's operation, and now Tait's operation. And why not, when speaking of an operation which is performed more frequently, perhaps, than all these others combined, and which has been productive of so much good—why not call this surgical procedure after the name of its eminent author, and say Emmet's operation? Jenks writes me from Chicago that he intends to drop trachelorrhaphy in the future, and in writing or speaking say Emmet's operation.

The importance of the operation—Emmet's mode of performing it—and the various modifications of his originally-described plan of procedure, have all been voluminously written up. The indications for the operation, the preparatory and after-treatment, have been discussed in the more recent text-books, and in nearly every medical journal and society in the country, until all questions in regard to it seem in a fair way to be definitely settled.

Upon its more remote effects, however, there has been very little evidence recorded. The inquiry has arisen in many minds, what is or will be the condition of the uterus, say one, five or ten years after a laceration has been successfully restored by Emmet's plan? Only here and there has any record been made of facts which would enable us to give an intelligent answer to this question. Our efforts to defend the operation against the attacks of those who would charge evil against it, upon what is called negative evidence, have been somewhat crippled by our inability to point to recorded facts showing the after-effects of trachelorrhaphy, whether for good or evil.

Thus one writer searched the records in the great

library of the Surgeon-General's office and immediately writes to the *American Journal of Obstetrics* (January, 1883) that "he has endeavored to collect all the cases where, after the operation for laceration of the cervix conception took place and the condition of the parts after delivery were noted."—"Fancy my astonishment," he says, "to find throughout all the literature of the Surgeon-General's office touching this particular point, *eleven cases only recorded*."

He then quotes these eleven cases from the various reports, to which he adds three of his own, making fourteen in all, and refers to the fact that Goodell had only reported four cases out of 113 operations, where he had known pregnancy to follow the operation, and then jumps to the astonishing conclusion, which he says "is deducible from the statistics furnished, that repair of laceration of the cervix uteri is usually followed by sterility." The inference being that it was caused by the operation. He also states from similar evidence as his second conclusion also "deducible from the statistics furnished," that the character of the labor is unusually severe and protracted, and that in a large percentage, laceration occurs a second time.

Our English cousins, Tilt and Savage more especially, have criticised Emmet's operation with much sharpness, displaying in their discussion of the subject as much ignorance of our literature as of the proper limitations of the operation, as pointed out in an able paper of Dr. Charles Carrol Lee, of New York. (See New York *Medical Journal*, Sept., 1881.)

As Dr. Howard,¹ of Baltimore, and Jenks,² of Chicago have ably answered the criticisms and unfair strictures of these gentlemen, I will not occupy your time with that branch of the subject, but keep to the subject of its immediate and remote effects.

If this surgical procedure, which has received the endorsement of all good gynecologists the world over, who have properly tested its merits, is followed by sterility as a necessary consequence, or, if it is the cause of severe and protracted labors as claimed, and if re-laceration occurs from any reason fairly traceable to the operation itself, I thought such facts should be placed on record, as a warning to this and future generations, together with additional facts relating to the occurrence of primary and secondary hæmorrhage, cellulitis, peritonitis or death, and the proportion of cases stated in which these accidents occur. Many have regarded this as one of the safest and most unusually successful operations in surgery.

In order to learn these facts I addressed a letter to a number of gynecologists, asking for information upon these topics, with the statement that I desired to place their replies upon record for the purpose of supplying the missing link, so to speak, in the history of this subject. In my letters of inquiry I requested information upon the following points:

1. Number of operations performed.
2. Number of times pregnancy has followed the operation.

¹ Report of the Sections of Obstetrics and Gynecology to the Medical and Chirurgical Faculty of the State of Maryland, pp. 17, 10, 1883.

² Contributions to Surgical Gynecology, by E. W. Jenks in 1882. Transactions Illinois State Medical Society, vol. xxxii.

3. Character of the labor. Whether unusually severe, protracted or natural.

4. In what percentage of cases did re-laceration occur. Whether in the same place or on the opposite side.

5. Have any of your operations been followed by secondary hæmorrhage, pelvic cellulitis or death?

I have made a table of the replies of twenty-six gynæcologists which I herewith present to the Section. It is impossible to do justice to my correspondents by so condensing their replies as to simply fill up the blank spaces in a table covering the points upon which I made inquiry.

In some instances a letter of six or eight pages

does not give the information desired in such form as to be fairly expressed by figures, and I shall be compelled therefore in justice to them and the subject as well as to you, to read extracts from the irreplies relating to certain facts or figures, as an appendix to my paper.

Thus, for example, Dr. Emmet states that he has known pregnancy to occur often, but as he does not practice obstetrics, he is unable to state the character of the labors following. This statement is the rule rather than the exception in the answers to my letters of inquiry. The necessity for more full extracts than could be expressed in a table becomes obvious.

NAME OF OPERATOR.	NO. OPERATIONS.	NO. OF PREGNANCIES.	CHARACTER OF LABOR.	CASES OF HÆMORRHAGE.	OF CELLULITIS.	PERITONITIS.	DEATH.	RELACERATION.
Emmet.....	About 600	Often.	3	Several.	..	o	3
Thomas.....	In last three years in his Sanitarium alone	Often.	See Letter.	o	..
Goodell.....	102	A few.	Normal.	3	Very rare.	Very rare.	3	3
Berlin.....	211	Has never happened to attend a patient who had been operated upon.	o	..
Scott.....	125	Frequently.	Not Severe.	A few.	A few.	o	o	Some.
Chadwick.....	12	1	o	o	o	o	..
Byford.....	Over 50	Only knows 3	Does not practice obstetrics. Thinks the operation cures sterility.
Jackson.....	118	9	4 natural. Don't know about others.	4	3	o	o	Don't know of any.
Smith.....	See letter.	4
Mann.....	Over 50	4	O. K.	o	3	o	o	o
Baker.....	250	Several.	o	o	o	o	5

Engleman.....	See letter.	o	o	o	o	2
Howard.....	A great many.	Several.	Can't say.	o	o	o	o	..
Total.....	3,111	77

Most gynæcologists are not practicing obstetrics, and consequently do not know of their own knowledge the ultimate effects of their work. As they do not follow up their cases, in most instances, they cannot say how often women upon whom they have operated have become pregnant, or state the character of their labors.

Emmet and Goodell both express the opinion that the preventive measures adopted to prevent conception are largely the cause of the apparent sterility following trachelorrhaphy, and Emmet states that after much careful thought he does not believe that the operation has anything to do with producing

sterility when it is properly performed, and yet if we relied upon cool statistics to prove this, we should utterly fail, as both those distinguished gentlemen after about eight hundred operations report less than a dozen cases of pregnancy following of their own knowledge. Those who take the opposite side of the question will also fail to establish their points by simple reference to statistical tables; while unexplained figures would seem to aid them, the subjoined letters clearly show the correctness of my position. We must of necessity then look elsewhere than in statistical tables for the true explanation of the implied sterility.

It is apparent that a majority of the cases have been operated on in charity hospitals and in consultation practice, and when patients are discharged cured, they have passed entirely from observation, and their subsequent histories are unknown. It is not logical reasoning therefore to argue that *because* they are not known to have borne children, they were *therefore* sterile, and made so by the operation. In the replies to my inquiries this point, I think, is made emphatic. It also appears that as many women are past 40 when they apply for treatment, they have already reached an age when they are not likely to become pregnant, and furthermore that as they have gone through so much suffering, the result of childbirth, before obtaining relief, in many instances they are known to have used precautions against future conceptions. It frequently happens also that the operation is performed on widows. I have operated upon several of this class.

So many women have borne children who have sustained the injury under discussion, that it cannot be honestly claimed that they were sterile before the operation. Those who claim that the operation causes sterility should not operate upon any woman wishing to have more children, unless they hold the erroneous opinion of a previously induced barrenness, and believe, therefore, that trachelorrhaphy could not add to the existing trouble.

It is thus manifestly incorrect as well as unfair to judge the question of apparent sterility by purely statistical evidence. One cannot properly say that all women not known to have conceived after this operation were made sterile by the operation, and argue from such premises against the propriety of its future performance. I have presented evidence from hitherto unpublished sources of more than 100 cases of pregnancy following Emmet's operation, and that the labors have not been unnatural, and re-laceration was a surprisingly rare occurrence. If re-laceration *were* to occur upon the opposite or same side, I fail to see why, if the indications for the operation were prominent and unmistakable, it should not have been performed and the patient relieved from present suffering and future danger. If it should tear out, it could be easily sewed up again.

If a patient requires perineorrhaphy for her safety or comfort, no gynecologist, it occurs to me, would refuse to operate for fear of a possible re-laceration of the perinæum in some future labor. The surgeon's duty is to relieve present ills, and not stay his hand for fear of those he knows not of.

It should be taken into account also that Emmet's operation, as all other operations in surgery, may be improperly and unskilfully done. It is undoubtedly true, as stated by me in a recent paper,¹ "that errors in judgment *would* occur, and disrepute be brought upon a very valuable operation by its unwise, unskilful and too frequent repetition." There is no doubt but this operation is resorted to more frequently than is required, but this occurs in the history of all new operations. Sufficient opposition is thereby elicited to finally confine it within its "proper lim-

itations." Emmet has stated that he now performs it only once where he formerly did it ten times. He finds that by curing an existing endometritis and cellulitis the tissues which had rolled out and produced an ectropion, giving the appearance of a considerable laceration, are curable by appropriate treatment and an operation becomes unnecessary.

There are conditions, however, of catarrh of the cervical mucous membrane, which Van de Warker claims are cured better by the operation than by any other means. If any catarrhal endocervicitis remains afterwards, he claims that he has rendered it more amenable to treatment. I learned from him that it was unnecessary to wait for the cure of this condition by a long, frequently unsuccessful and always troublesome and expensive course of treatment, but that it was better to proceed at once, where an operation is required. In stating this point in a former paper, it appeared as if I had "always" held this view, and that my friend had recently confirmed it in an article in the *American Journal of Obstetrics*, July, 1883. I desire to state that I was following *his* lead, and that the priority in this new departure belongs entirely to him.

When a surgeon cuts away too much of the tissues of the cervix, thereby destroying its future dilatability, to a certain extent, or leaves too little undenuded tissue for the new cervical canal, in a bi-lateral laceration, thus producing a veritable stenosis, or sews up the entire cervix, leaving no canal whatever—as I am informed has occurred—the blame should be placed where it belongs.

The fault lies not in the operation, but in the hand which performs it.

Howard says, in the article already referred to, and his language I now adopt, "that favorable results have not always been attained by trachelorrhaphy, is nothing more than what we occasionally witness in respect to other operations, alike in general and special surgery, although universally approved and practiced. Alternately favorable and unfavorable results from trachelorrhaphy arise from several causes.

1st. The conditions and indications for the operation have not been clearly defined, or else disregarded.

2nd. Proper preparatory treatment has been overlooked or inefficiently conducted.

3rd. The operation has been, from inexperience, or want of dexterity, clumsily done. Some persons can never perform a delicate or serious operation, and whenever they attempt it, they remind one of a bear-dance or elephant-waltz in a travelling menagerie. This is especially true of plastic operations."

I think the feeling has prevailed among the people, and to some extent among physicians, that the cervix is so liable to re-laceration in subsequent labors that the operation should therefore not be performed until after the menopause. In reference to this subject, I would venture to express the belief that the cervix is just as liable to laceration after the operation as before, and no more. The frequency of cervical laceration has been placed as high as one in every six women confined, by so excellent an observer as Goodell. Emmet places the percentage at 33 ;

Mundè, 22; Pallen, 45. The line of union is so perfect in successful cases, that Hunter states (*American Journ. Obstet.*, Jan., 1883, p. 69) that a few months after restoring a lacerated cervix, he could not determine by the touch, where the injury had been. The tissues seemed to be no harder than the surrounding tissue. I can confirm this statement after many examinations. Dr. Hunter, in same journal, p. 68, states that he delivered a woman in June last, on whom he had performed an operation for a severe laceration of the cervix, and also for a complete laceration of the perinæum. The child was born at full term and weighed over seven pounds. Neither the cervix nor the perinæum gave way. This was only one of *several* which he had seen in which no injury was done the repaired laceration at subsequent labors.

In the same discussion, Dr. Skene stated "that he had seen *several* cases of successful delivery without further injury after operations for laceration of the cervix."

Dr. A. S. Clarke in same discussion remarked that about five years ago, he assisted Dr. Skene in restoring a cervix badly lacerated bilaterally, and he was sent for in June last, to deliver the same woman; but when he arrived the child was born, labor having been very rapid. The child weighed ten pounds. There was no laceration.

The cause of the re-laceration when it does occur is supposed by some to reside in the hardened cicatricial tissue said to remain after the operation. But Hunter has shown us that none is found a few months afterwards, and even if there were, it is difficult to understand, from the location it must occupy, how it could interfere with dilatation.

If it were circular, it would do so, whenever present, but being lengthwise, cannot interfere much, if any, and Clarke says, in reference to the rapid birth of this ten-pound child, that "if any cicatricial tissue from the old operation had been present, he thought it certainly would have given way." Dr. Hanks stated that he had delivered *several* women whose lacerated cervixes he had sewed up, without any injury resulting. As bearing upon the supposed presence and influence of cicatricial tissue, in causing protracted labor, and re-lacerations, I ask attention to the following remarks of Dr. C. C. Lee (same discussion): "Two years ago, Dr. Lee performed an operation in the Woman's Hospital on a patient who had a very extensive double laceration of the cervix, so that very little of the true cervical tissue remained after its repair. An excellent result was obtained. He was particularly interested in the case, as the laceration had been so extensive, and she was a young woman, and expected to bear more children." She was subsequently attended in a confinement by his associate, Dr. Swasey, who reported "that no laceration whatever had occurred." "Dr. Lee examined her very carefully afterward himself, drawing down the cervix with the tenaculum, but he was unable to find any laceration. Dr. M. A. Pallen stated that "with regard to subsequent delivery, without injury, after operation on the cervix, he had met with *several* such cases—at least half a dozen in

his own experience. Some patients he attended in two subsequent labors, and no laceration took place. Last year he closed a double laceration of the cervix, and in July last attended the patient in labor. No laceration occurred either of the cervix or of the perinæum, both of which he had operated on for laceration.

In the *New York Medical Journal*, Vol. xxxviii, 1883, p. 48, a discussion in the Philadelphia Obstetrical Society is recorded, in which twenty cases of pregnancy following operations by Drs. Baer, Gittings, Goodell, Montgomery and others. In nearly all the cases a normal labor occurred, unaccompanied by re-laceration.

There are some facts to prove that this is not so universally safe an operation as many have supposed it to be. While my question in regard to the occurrence of pelvic cellulitis and peritonitis was answered by eight correspondents in the negative, four report eight cases, and six say they have had "several" or "a few" cases each, and eight do not reply to the question at all.

Drs. Emmet, Scott of San Francisco, and others, say that where it has occurred, it has generally been traceable to some error in the operation, such, for example, as failure to entirely cure an existing chronic cellulitis, so that when the uterus was drawn down to the vulva, the over-stretched tissue became irritated and an acute attack resulted. Seventeen cases of hæmorrhage are reported—one fatal case and several not yielding to ordinary means, including styptics and the tampon. Sutures had to be introduced beneath and around the bleeding vessels before the hæmorrhage could be controlled.

Seven deaths resulting immediately from the operation are reported, and I have heard incidentally of three others not included in this table, but within the knowledge of some of the writers—making ten in three thousand cases; that is, three and one-third to a thousand, or about one-third of one per cent. if we include the ten cases—three deaths occurred in the practice of one man, and he so good an operator as Goodell, as set forth in the table already reported.

I think I have proved, from the best of testimony, that Emmet's operation does not cause sterility when properly performed, that re-laceration is no more prone to occur after the operation than before, and that severe or protracted labors do not follow as a consequence; that it is not without its dangers, ten deaths occurring in a little over 3,000 cases, besides a number of instances of hæmorrhage and cellulitis not fatal. I believe the cervix is operated on in many cases which might have been cured by proper treatment; and I believe also that the operation, when properly performed and clearly indicated, is one of the greatest improvements of the age.

89 MADISON AVENUE,
NEW YORK, March 8, 1884. }

DR. J. T. JOHNSON, WASHINGTON, D. C.:

Dear Doctor:—I wish I knew how many times I have operated for closing a lacerated cervix—certainly not less than 500 or 600 times in the past

twenty-two years. I have never regretted doing the operation, and have often wished that I had performed it. I believe that I have kept many a woman out of the lunatic asylum, and saved many a life from phthisis. I have never lost a patient from or after the operation. Quite a number have had more or less cellulitis after the operation, which could generally be traced to some imprudence or to error in judgment on my part in operating before the case was properly prepared. I have known of three cases where serious hæmorrhage has occurred after the operation—one in my private hospital, where oozing went on for several hours after the operation, and was stopped by a deeper stitch, a recent case in my service at the Woman's Hospital, coming on about two weeks after the operation. It was a very serious case, and was stopped with difficulty by the use of the tampon. The third case was in Dr. Pallen's practice several years ago, when the bleeding had been going on for some two days after the operation, and the woman was very nearly losing her life. I was called in, and stopped the bleeding by untwisting the sutures and introducing another lower down. I do not believe the operation has anything to do with causing sterility. When a woman has remained sterile afterward, it has been due to the existing cellulitis, or to the damage done by the previous inflammation including the tubes. I take great care in preparing my cases for the operation, and pregnancy has occurred so often after I have operated, that I am fully convinced my view is correct. I do not recollect of more than three or four cases having returned with a second laceration, and have examined a large number of old patients where a fresh laceration did not occur, and some have borne a number of children after the operation. I only wish I had the data to give you, but I have been too busy a man to keep them, and can only give my impressions.

In writing on this subject you may do much to correct the general abuse into which the practice of the operation has fallen. Everybody is performing it, and very few are doing it with any purpose except to close a fissure. The operation should never be done without there are marked symptoms calling for it, and the case should be properly prepared before it is done; for until the cellulitis has been removed, which causes the parts to roll out, it is impossible to decide, except in a very few cases, if the operation is needed or not. A large fissure will sometimes disappear as the parts roll in again, as the cellulitis clears up. Where there are marked reflex symptoms, very few clear out properly the dense tissue from the angles, and I operate on a large number of cases with marked benefit when the operation has already been done by some one else and the patient had been disappointed in the result. I wish you all success.

Yours very truly,

T. A. EMMET.

294 FIFTH AVENUE, March 13.

My Dear Doctor:—I regard trachelorrhaphy as one of the most important advances that have been made in gynæcology within a quarter of a century. After the closure of a lacerated cervix I have often

found pregnancy to result where sterility existed before. On the other hand sterility is produced by it in some cases where the cervix has been sewn so tightly that it is impossible to pass even a uterine probe.

I am sorry that I have no statistics to give you of the operations I have performed either in the Woman's Hospital or in private practice. You can form some idea of the frequency with which I perform trachelorrhaphy when I tell you that in my sanitarium which was opened three years ago, I have done the operation one hundred and two (102) times. As to my other cases I have kept no record. In a word I regard trachelorrhaphy as an operation of extreme value, but an operation that is often performed where there is no real necessity for it.

I am very glad you have taken up such an important topic, and regret that I cannot give you more information.

Yours sincerely,

T. G. THOMAS.

47 E. THIRTY-FOURTH STREET, }
NEW YORK CITY. }

Dear Doctor:—I have performed trachelorrhaphy between 200 and 300 times. I have no statistics showing the frequency with which the operation has been followed by pregnancy, but know that it is of common occurrence. Labor in such cases has not proved unusually severe. I should say that re-laceration was a pretty common event, though of course not a necessary consequence of the operation.

I have had one case of secondary hæmorrhage in the hospital, but never in private practice. I have seen slight attacks of cellulitis occasionally follow the operation. I have had one fatal case. This occurred at the hospital. I had left my operating bag at home, and tried to shift with instruments from the hospital drawer. I have no doubt that the knife used had not been properly cleaned. At any rate lymphangitis started from the wound and death followed.

Very truly yours,

W. T. LUSK.

280 W. FOURTH STREET, }
CINCINNATI, March 11, 1884. }

My Dear Doctor:—I have operated about 200 times. So far as I have been able to discover, sterility has not resulted from the operation. In a good per cent. of the cases sterility was cured, not in all. I have attended several of my cases in subsequent labors.

In two cases dilatation was tedious but ultimately complete. In the others dilatation was natural. In no case did re-laceration occur.

So far as I have been able to learn, other physicians who have attended during labor, cases upon whom I had made the operation, have had similar experiences.

The operation can be, and doubtless has been, greatly abused. But confined to appropriate cases and carefully done, it is in my judgment one of inestimable value.

In 1876 I adopted the method of allowing free bleeding from the cervical vessels during the cutting stages of the operation, which not only greatly facili-

tates the more perfect co-aptation of the edges, but renders the introduction of the needle easy.

Of still greater value is this bleeding in reducing the congested and hypertrophied cervix.

Very truly yours,

THAD. A. REAMY.

CHICAGO, March 6, 1884.

Dear Doctor :—Your letter in reference to trachelorrhaphy is received. I have probably operated over fifty times. The immediate results have been fairly good; but I have not been able to follow up my cases so as to collect facts relevant to the points which you are investigating. I do not practice obstetrics. This may be one reason why I have not been able to get information such as you desire. I have in mind, though, three cases of recent date which have been succeeded by pregnancy. I have gotten the impression, without any definite data upon the subject, that the operation, when required, restores fertility instead of impairing it.

I am very respectfully yours,

W. H. BYFORD.

PHILADELPHIA, March 13, 1884.

Dear Dr. Johnson :—I have operated on two hundred and eleven (211) cases of laceration of the cervix uteri.

As I am not engaged in general practice, and do not attend obstetrical cases except as a consultant, I cannot keep track of cases in which pregnancy occurred after the operation. My opinion is that pregnancy would have happened more frequently in some of my cases, were it not that, for fear of a second laceration, preventive measures were probably resorted to.

No unusual difficulty occurred in the labor of those who became pregnant. In three the cervix was again torn, but in only one was the rent bad enough to need a second operation. The tear originally was a bilateral one, but this time the left side alone gave way.

Three of my cases were followed by secondary hæmorrhage, which was controlled by a sponge tampon. This did not at all interfere with primary union, which was excellent in all. The woman in every instance was fat and plethoric.

I have lost two cases, both of them in hospital practice. One died suddenly from heart-clot on the fifth day after the operation on a cervix with supravaginal elongation. The other, immediately after the operation, inexplicably became comatose, and after lingering in that condition for several days, died. The autopsy revealed a syphilitic gummy tumor of the brain. Neither of these had any fever or any inflammation whatever. A third death ought perhaps to be reported, which occurred in my private practice; but it was in a case in which both cervix and perineum were restored in one operation. The lady was delicate, the operation a prolonged one, and followed by excessive vomiting which lasted for several days. She died very suddenly on the fifth day with symptoms of embolism. This very unfortunate result has made me chary of performing both operations at one sitting.

On very rare occasions I have had pelvic peritonitis and cellulitis to follow the operation, but this occurred only in cases treated at a general hospital; never in cases operated on at their own homes or in my private hospital. All these cases recovered, and with perfect union of the wound. One of them, however, ended in an abscess, but the occupant of the bed next to hers broke out with erysipelas a few hours after she had been operated upon.

I deem the operation of trachelorrhaphy to be a most valuable one—one for which I feel under lasting obligations to Dr. Emmet. Yet I cannot but think that it is performed altogether too frequently.

Very respectfully yours,

W. M. GOODELL.

Dr. James R. Chadwick, of Boston, writes me that he "believes the operation to be an improvement upon previous treatment of such cases in a very limited number of extreme cases. My cases which have not been operated upon have borne more children than those operated upon."

Prof. Skene says "in a general way he believes the operations tend to cure sterility instead of producing it, by restoring the womb to a natural physiological condition capable of going through the period of child-bearing in a healthy instead of a morbid condition."

Dr. Skene thinks his method of operating a great improvement on Emmet's plan and much more. [See American edition Holmes' Surgery, vol. ii, p. 1014.] He "seldom takes more than thirty minutes for the operation, and in a recent case of bi-lateral laceration in which he operated with a perfect result, inserting six sutures, the time of operation by the watch in the hand of his assistant Dr. Thallon, was ten minutes and thirty seconds. Most of his cases of cervix alone stand the operation without anæsthesia.

Dr. Edward W. Jenks, LL.D., of Chicago, writes me that "I have performed many operations for laceration of the cervix uteri from and in various parts of the country, and my inability to say what effect the operation may have had on subsequent labors. * * * I have not known of a single case of sterility in consequence. One case came under my observation where the operation had been improperly done, or rather too much had been done by the surgeon, as the cervical canal almost to the os-internum was closed, and to the left margin of it there was an opening that barely admitted a very small probe. The patient was not relieved of any trouble for which the operation had been performed and was sterile until I opened the closed canal, after which she was entirely cured of her nervous trouble and soon became pregnant, and had an easy labor at full term without any re-laceration. I have been unable to hear of any instance of severe or protracted labor consequent upon operations I have performed for lacerated cervixes."

Dr. William H. Baker, of Boston, says in reply that "I have no time to be exact, but I will say that I operated quite a number of times, perhaps 250, and I am glad to state that I cured sterility instead of producing it. Several of my cases have been

confined since and re-laceration occurred in five or six cases. I believe the operation one of the greatest improvements of the age" (entire letter.)

Dr. Engleman, of St. Louis, endorses most heartily Dr. Baker's letter, says he has never produced sterility by the operation, but on the contrary has cured it.

Dr. M. D. Mann, of Buffalo, after giving me the figures stated in the table, agrees with Dr. Baker that "the operation is one of the greatest improvements of the age," and adds, "I think one reason why pregnancy does not oftener follow is that many of the women are in the forties, an age when pregnancy does not occur so frequently."

Dr. Albert H. Smith writes: " * * * I have done so many of the cases in the Lying-in Charity Hospital, and so many in consultation in other men's practice, of which I have kept no histories, that it will be impossible to give you a full statement. * * * I am against the theory as to the resulting sterility. Three weeks ago I attended in *one week three women* at full term, and one miscarriage in patients *on whom I had performed trachelorrhaphy*."

Dr. A. Reeves Jackson, of Chicago, says: " * * * I know of only nine cases out of 118 operations where pregnancy has taken place. Although as many of my patients have come from distant localities, and I have heard nothing from them since, I would regard any estimate based upon such data as quite or almost useless.

"In four cases of the nine in which pregnancy followed the operation, there was no re-laceration; of the others I have no information. I do not doubt that a laceration sufficiently extensive to produce erosion of the cervical lining or enlargement of nabothian glands or endometritis, is a cause of sterility, and that the removal of those conditions by trachelorrhaphy in such cases would be the quickest and surest means of curing the barrenness.

"Dr. Paul F. Mundé, of New York, writes me on the 24th of April that out of 137 operations he has known of thirteen cases which were followed by pregnancy, and says he does not believe the operation has any effect in the causation of sterility, and that it has no injurious effect whatever upon labor. Cannot give exact figures in regard to the percentage of cases of re-laceration, but it does not occur, as a rule, any more frequently than it does in first labors. If it occurs, thinks it is usually in same place."

The explanation of the small number of pregnancies known to me as following operations performed by me, is found in the fact that the cases were brought to me as a specialist by other physicians, and were never again seen by me. I have no doubt that pregnancy occurred after the operations quite as frequently as it does under ordinary physiological conditions.

So far as known to me, the character of labors following trachelorrhaphy have exhibited nothing unusual. Think about 20 per cent. suffer re-laceration in subsequent labors. Dr. Mundé thoroughly concurs with those who regard this operation as one of the greatest improvements of the age. Thinks "it cures sterility instead of producing it," from his own sufficiently large experience.

Dr. Fanny Berlin, of Boston, writes 4th of April that she has performed the operation more than fifty times, but has never had one return pregnant, "yet she is not prepared to say the operation produced sterility."

1st. Because many of those operated on had passed the time of child-bearing—in fact the majority had.

2nd. Many do not wish to conceive again, and use means to prevent conception.

Extracts from a letter of Dr. John Scott, of San Francisco: "I have performed the operation 125 times. Not being engaged in obstetric practice, I cannot state how often pregnancy has followed, but I have known of its occurrence so frequently after the operation when the woman had not conceived for two and more years, that I regard it as a frequent cure for sterility.

3rd. "I have heard that the labors were not severe or in any way rendered more difficult by the operation, except in two or three cases where sufficient os was not left after healing, and then the delay was only temporary.

4th. "Not being engaged in midwifery practice, my answer to this query is valueless. I have, however, known of re-laceration taking place in some of my early cases, but I believe it was owing to the operation having been done improperly. * * * Simple as the operation appears, I look on it as most difficult to perform well, and its success depends largely upon its being thoroughly well done."

"I agree with you in considering the operation one of the most invaluable ever invented and entitling its author to the gratitude of the profession and the public."

Extracts from letter of Dr. H. P. C. Wilson, of Baltimore * * * No operation in Gynecology has given me more satisfactory results than Emmet's operation on the cervix * * * I cannot recall a single case in which I have reason to think sterility has been produced. I can recall a case where pregnancy occurred three months after the operation, the woman not having been pregnant for 12 years previously. The woman had been in wretched health for several years before the operation. She was safely delivered of a fine child without any laceration and is now in good health. * * * No unpleasant results have followed any of my operations. I believe it is one of the safest operations in surgery. I have kept very imperfect notes of my cases and a great many have not been noted at all, but if I had time to look over those I have, I am sure I would be able to give you more cases in which I have cured sterility by this operation. I have never had cause to regret having performed this operation, nor am I aware that any of my patients ever regretted having it done."

Dr. R. Stansbury Sutton, of Pittsburgh, closes his letter as follows:

"I believe that in cases where the laceration is very slight, to all appearances, often cicatricial tissue in the cleft is acting as a neuroma and in such cases I have had good results—relieving general nervous disturbance.

"I have modified the operation of Emmet in this—I never use silver sutures. In my first 40 operations

I did, but for a year have used only "Salmon gut" sutures—*never cutting them short* but leaving them to hang from the vagina—to *act as a drain*—and to make it an *absolutely painless and easy operation*, to remove them at the end of a week. Nothing would induce me to again adopt silver sutures in cervix surgery."

Extracts from letter of Dr. Wm. T. Howard, of Baltimore. 1st, "I can say little on the influence of Trachelorrhaphy in causing sterility or in curing it. In an immense majority of my cases I have never heard of them afterwards, as about two thirds of all my operations are on persons from a distance. It seems to me, however, that this matter is not likely ever to be decided. For it depends entirely on whether the operation is well or badly done. I have long been of the opinion that of all the operations done in gynecology, this is oftenest badly done.

If well done—if the os externum is well made—not too small and a sufficiently large undenuded track is left, for the cervical canal, the operation cannot possibly interfere with the migratory habits of the spermatazoa—and as a lacerated cervix is one of the most prolific causes of a copious irritating leucorrhœa which dear Sims proved kills the Spermatazoa in numerous instances, it follows of necessity that trachelorrhaphy ought often to cure sterility where well done.

2nd, In regard to the effects of trachelorrhaphy on labor my experience is small, since I have for years been drawing away from obstetrics—and most of the cases I see are in consultation. * * * A few days ago, however, a lady presented herself upon whom I did trachelorrhaphy about two years ago for a bi-lateral laceration.

She had at that time two children, both born without the use of the forceps.

Whether laceration usually occurs in subsequent labors I cannot say. It did in one case partially on the right side but not in the same place—but was not extensive enough to demand another operation.

4th, In regard to the number of my operations I cannot speak with any certainty, since I have never kept a list of them. But as I was the first to do the operation in this city, and had often operated 3 or 4 years before the publication of Emmet's first paper on lacerations of the cervix, I must now have operated a great many times.

5th, I have never had troublesome hemorrhage *in nor after* any of my operations, and so far as my memory serves me, never pelvic cellulitis in any case."

DISCUSSION.

Dr. Gordon, of Maine:

Mr Chairman:—There are two or three points in this paper which I wish to endorse most heartily. I have made the operation about 175 times. I have made it where I have no doubt Dr. Emmet would say it ought not to be made; I have no doubt that I have made it where a great many would say it ought not to be made. But I will say this, I believe that all the patients I have operated upon which were in the bearable stage, at the stage in which they would bear children, have been just as liable to and have become as frequently impregnated after the operation

as before. I believe it conduces to fertility rather than to sterility. I believe that the operation is important for two things—not only for the symptoms that we usually operate for (backache, pain in the hips, and the usual train of symptoms that everybody admits we should operate for), but by far the most important thing is to reduce hyperplasia of the uterus. I go further than that. I not only make an operation where there is a laceration, but in all cases of hyperplasia of the uterus I take a V-shaped piece out of each side. I have made the operation and taken out the V-shaped piece from the cervix for hyperplasia, where there was no laceration. The trouble is, we do not do enough in making this operation. In the first place, your scissors should be sharp enough that with one cut you take a complete piece off of each side. I believe the man who makes more than one cut on each side, in making an operation for lacerated cervix, for each particular side which he denudes, makes a mistake. The great trouble is with the ragged edges that are left. We are too much afraid about cutting out enough.

While I am in a sense a general practitioner, I avoid obstetrics as much as possible. A man who has not anything better to do than to sit up nights and attend to labor cases, has very little, comparatively, to do, after he has been in practice twenty-eight years, as I have been, and consequently I avoid every case that I possibly can. Yet I have had an opportunity to follow up several cases where pregnancy has occurred, and in but one single case has there been re-laceration, and that was upon the left side in a bi-lateral case. The labor was just as easy, the patient acknowledged, as she had had in either of her previous labors. So I believe that if this operation is done as it should be done, you get no more interference with the labor than if there had been no laceration at all; and I believe that in the operation, where there has been an existing hyperplasia for any length of time, the patient, on account of that operation, shows an easier labor.

Dr. Woodward, of Vermont:

Mr. Chairman:—I wish to call the attention of the Society to one point in this operation which I think is very important. It is this: I think myself the only danger resulting from the operation is cellulitis or peritonitis, endorsing all the other propositions that have been brought before the Society. We sometimes find there is more or less tenderness in the cellular tissues about the uterus, and I generally leave the uterus alone. I do not draw the uterus toward the vulva. I believe it is an almost universal custom to draw the cervix toward the vulva, but I find where there is any tenderness about the cervix it is best to leave the uterus alone, and I have good results in following that rule. I believe that as a rule it would be well to follow it to obviate the tendency or danger of cellulitis. I have adopted it in performing about sixty operations.

Dr. Harvey, of Indianapolis, Ind.:

Mr. Chairman:—I want to address myself to one point in the paper, and that is in regard to this operation being performed oftentimes when it should not be. I want to differ with the views which have

been expressed on that point. If laceration of the cervix exists it should be repaired. That is a point that I want to make. If there is some other disease of the uterus which causes dilatation of the os uteri, that is not laceration; and if gentlemen make mistakes and operate where laceration does not exist, the operation is not to be censured for such mistakes. Why should the uterus be permitted to remain in a state of slight laceration any more than any other organ in the body? Suppose the angle of the eye were torn, is there any surgeon who would not advise some operation for relief? So if the nose were torn. Instead of backing down in regard to this operation, as Dr. Emmet and others have done, and admitting that it has been resorted to too much, even by skilful operators, I say that it has been too much neglected. Even in mild cases, where gentlemen say it should not be performed, but the case treated by cauterization, there the beneficial effects have been shown. There you can cure the case before hypertrophy of the mucous membrane takes place.

I have seen four cases, within the last year, of the cervix where I could trace distinct forms of laceration described by Emmet, not deep, not bi-lateral, where both lips have been torn out; but in stellated form. Therefore I say that we should operate in every case, and in doing so we are honest both to our patients and to ourselves. You take a case of laceration. How do you cure it? With hot water and cauterization, and in six months the doctor thinks the patient is well, and the patient thinks she is well, whereas in three or four months she goes back again, while in one hour's time, by a slight operation, he could have cured her permanently. I think, gentlemen, there is no one operation that has been performed, that has done so much to relieve suffering woman as this which—I agree with Dr. Johnson in terming—"Emmet's operation."

Dr. Englemann, of Missouri :

Mr. Chairman :—I think we are indebted to Dr. Johnson for so thoroughly analyzing this operation. I think it is the most wonderful of all gynecological operations. I do not think it matters whether we repair the laceration of the cervix, but all the results which come from that, both local and general, we must relieve. I do not see why it should be necessary to operate upon a lacerated cervix simply because it is lacerated. There are some cases of laceration of the perinæum which we do not operate upon, and there are cases of similar laceration of the cervix that we do not operate upon. We simply relieve the symptoms caused by it. There are large lacerations which do not affect the system at all. You have all seen patients with a large torn cervix who are in no wise ailing, and yet there are some with a slight laceration who suffer much. I see no reason why we should operate upon a lacerated cervix unless there are symptoms shown. It is not the surgical union, the surgical result, which measures the benefit accomplished, but it is the important benefit in the local and general condition of the patient, and for that reason I say it is a most wonderful operation—closing that small laceration will change the appearance of affairs completely. I do not believe

there is any other operation on any other part of the body which will so thoroughly affect the system, and it is by that we measure the results—not by the union or by the local results. When I say that it is not the local condition which tells us whether we should operate or not, I mean it is not the laceration which forces us to operate, but the symptoms.

Dr. Quimby, of New Jersey :

Mr. Chairman :—Just a word in reference to the effect of the operation on pregnancy. I have had one or two cases where women became pregnant after the operation who would advance to the third or fourth month and miscarry. I have laid each of those cases to the condition of the cervix, and somewhat, I thought, to the operation. How much that is the experience of others I do not know.

In reference to the operation I hold, (and I have examined over two thousand cases which have given me some experience in the treatment of that trouble,) where there is no trouble, no constitutional symptoms, when the patient appears to be in good health, where the uterus appears to be normal, with the exception of this laceration, (especially if it be slight,) I deem the operation improper, simply because it seems to be a species of meddlesomeness—an operation which does not seem to have a cause or a motive. Now I hold that all operations are for the benefit of the patient, and if the patient is not seemingly suffering from the laceration, the operation is not called for.

Dr. King, of Sedalia, Mo. :

Mr. Chairman and Gentlemen of the Section :—I heartily endorse and concur in the general sentiments of the paper and the points made. I do not think that the gentleman who read the paper made a single point that was not a good one, and I wish also to concur in the sentiments of Dr. Harvey, of Indianapolis. If it is true, as laid down by Emmet, that epithelioma is caused by laceration of the uterus, when a woman is threatened with this disease, why not cure that which lays at the foundation for it! Now, I have seen in my experience five cases of epithelioma, which were based upon the laceration of the cervix. I am in a country town in the west, and a woman in a country town in the west who submits to any surgical operation of this kind, is a pioneer in the profession as well as the surgeon who performs the operation. I have done the operation five times in the last year. I have seen the operation performed many times that number. All of them have recovered without cellulitis or peritonitis, and all of them have borne children. The statistics are meagre but the percentage is good. (Applause.)

Dr. Wathen, of Kentucky.

Mr. Chairman :—I wish to correct the statement of Dr. Gordon in giving Dr. Emmet as authority that laceration of the cervix is the sole cause of epithelioma of the cervix. No such inference can be drawn from Dr. Emmet's contributions to medical literature, nor do I suppose that any one who has seen many cases of epithelioma of the cervix would believe lacerations to be the sole cause, since we have cases of this character in women who have never borne children.

Dr. Gordon. How many?

Dr. Wathen. I do not know how many, but I have seen several, and I know that they have not borne children. And I cannot concur in the opinion of Dr. Harvey that in all cases where there has been a laceration trachelorrhaphy should be performed for the purpose of preventing epithelioma. If epithelioma be developed in the neck of the uterus as a result of laceration, it is because there is some local disturbance constantly acting as an irritant, or because there has been an effort at repair which has imperfectly filled the lacerated gap with cicatricial tissue of a low order of vitality—there is a mal-nutrition of the part—but if these conditions exist sufficient to cause epithelioma, then we would have local symptoms which would indicate the necessity of this operation.

In nearly every case of harmful laceration there is hyperplasia of the uterus, and in all cases where we are justified in operating to prevent epithelioma of the cervix, there are symptoms manifesting themselves that are easily observed.

Dr. Reamy, (having temporarily vacated the chair): I will only take a few minutes. It is in reference to one point that I desire to speak. The paper is upon the results of the operation. If the operation results in preventing cancer, that is one of the most important results. Now, I belong to those who believe that the operation ought to be done where the laceration is perceptible to the examination. I do not mean by this the laceration that converts the virgin os into the parous os, making a lip in front and a lip behind; but I believe with those who have claimed that every laceration that is perceptible, that amounts to a slit, ought to be closed, and ought to be closed without waiting for the symptoms.

If you can do a little operation so that a case of laceration will not become a case of cancer; if you can add one mite to the preventive measure in this direction, it ought to be done,—if for no other reason, it should be done solely on that account. The great Emmet (for no man admires his learning and skill more than I), has recently—I know not why—been going back on some of his most brilliant operations. I endorse the statement that it is too often done, but where there is laceration it is not done too often! (Applause.)

Brief remarks were also made—

By Dr. Nash, of Norfolk, Virginia, who endorsed the operation described by Dr. Gordon;—

By Dr. Moses, of St. Louis, Missouri, who stated that he differed with the views expressed by Dr. Engelmann, and believed that the operation ought to be more frequently performed for the actual damage to the cervix than for the general symptoms alone, or, certainly, quite as much so;—

By Dr. Eastman, of Maryland, who stated that he did not believe the operation should be performed in every case of laceration, and expressed the opinion that, in such an event, the gynecologists would run all the surgeons out of the country;—

By Dr. Kellogg, of Michigan, who stated that he had operated on about one hundred cases, in three or four of which the patients suffered painful menstruation after the operation, which they had not suf-

fered previously thereto; and stated that, in one of the last-mentioned cases, the patient had suffered from severe dysmenorrhœa before marriage;—

By Dr. Hawse, of Missouri, who stated that he did not believe the operation should be performed in every case of laceration; and

By Dr. Dudley, of Chicago, who differed with the opinion expressed by Dr. Engelmann; and stated in corroboration of the assertion made by Dr. King, that he had heard Dr. Emmet make the statement that he (Emmet) did not believe any case of epithelioma started without some primary laceration, and that he (Emmet) doubted the cases of epithelioma reported as having started without laceration.

Dr. Johnson (in reply):

I am exceedingly obliged to the gentlemen of the Section for the kind reception of my paper. Its views have been more generally endorsed than I expected.

With regard to the suggestion of Dr. Gordon, that the operation should be done with one clip of the scissors, I think it would be a most excellent plan to operate in this way if there were scissors that were capable of making that one clip successfully. The only ones I know that are capable of doing that, are the scissors invented by Dr. Skene, of Brooklyn, with which he claims to be able to make the denudation and finish the operation in ten or fifteen minutes. But no one has yet been able to acquire the dexterity which he possesses in the use of that instrument, even.

In cases of cellulitis, the operation should either be postponed until the chronic cellulitis is entirely cured, or, if any reason exist for operating at once, the uterus should not be drawn down, for fear of exciting a fresh attack, but do as Dr. Woodward suggested. But the operation is very much more difficult in cases where the uterus is not drawn down, as it is almost impossible to get at it in such a shape as to insert the stitches properly.

As to the remarks of Dr. Harvey and Dr. Reamy, in regard to sewing up all cases of slight ruptures of the cervix that are unaccompanied by any symptoms which demand relief, I cannot see that the patient could be properly or justly subjected to the risks which I have pointed out as occasionally accompanying the operation, when she is in a condition of apparent health, having no symptoms of any malady whatever. Those gentlemen recommend the operation for cases of slight laceration unaccompanied by symptoms, to prevent the development of symptoms hereafter, and to prevent, also, the development of cancer. The point I make is, that, if there are symptoms leading to the belief, in any way, that cancer is likely to occur from anything whatever which may be present at the time or from any hereditary influences, it would be a proper operation to perform, even if there were no symptoms. But as many women “get on” with a laceration, very well, and menstruate properly; have no distressing leucorrhœa or back-ache or other disagreeable symptoms; not being aware, themselves, that they have a laceration;—in those cases, I should say that there is no need whatever of performing it, but to await developments; and when

symptoms do arise that indicate the necessity for aid, I render that aid.

Dr. Quimby had reported several cases of abortion occurring after the operation had been made. Those were the result of his experience, but the results of those who have had a very much larger experience, and of those who have written on the operation, making up what we have of the literature on the question, show distinctly that abortion is very much more likely to occur before the operation than afterwards; that the operation is performed particularly for the cure of the habitual abortion into which the woman goes; and one of the best effects of this operation is to cure the habit of abortion.

The case reported by Dr. Kellogg, as I understand it, was one in which the patient suffered great dysmenorrhoea pains even before her marriage, and that her dysmenorrhoea could not be attributed to the operation or to its effects, in any way, because she had the pain before she was married and it returned subsequent to her having had children. It appears to me, therefore, that it had no connection whatever with the operation or the mode of performing it. [Applause.]

Dr. Kellogg: The patient had the pain before marriage, but had no pain after laceration. After the laceration was cured, the pain returned.

MEDICAL PROGRESS.

SURGERY.

VARICOSE VEINS IN THE HYPOGASTRIC REGION.—Dr. Troisier presented a case of this character before the *Société Médicale des Hôpitaux de Paris*. The patient, 33 years of age, was a mason and for three or four years had suffered from varices of the legs; he also bore upon his left leg the cicatrix of an ulcer which opened anew from time to time. About 2½ years ago he noticed that a large sub-cutaneous vein had developed on the anterior abdominal wall between the left inguinal region and the umbilicus. Since that time the left leg seemed heavy and showed some signs of tumefaction. Later (March 15) he felt pains in the legs and noticed that the varices had become hard prominent cords. A few days afterwards the varix of the abdominal wall became equally painful. On examination, the internal saphenous vein of the right side was found to be filled with coagulated blood; on the left side this coagulation did not pass beyond the middle third of the thigh, but on that side a large vein was seen to pass towards the groin, and after crossing the groin, to pass up the abdominal wall from left to right, forming a sort of horseshoe immediately below the umbilicus. This vein formed sinuositities that were very hard, and it was completely obliterated—it was about the size of a pen-handle. From its convexity, a non-sinuuous, dilated vein was given off. Further, just below the left groin, there was a permeable vein with several branches.

Here there was a true serpentine varix developed at the expense of the left sub-cutaneous abdominal vein, which commencing in the groin extended to the trunks at its saphenous opening, then extended to the opposite side by communicating with the right sub-cutaneous abdominal vein. What produced the development of this varix? He had received an injury to the left groin some three years before, but it healed perfectly and there was no trace of it left. Leaving that out of consideration no other cause could be ascertained as there was no intrapelvic tumor to press upon the iliac veins, and it would seem to be a case of spontaneous varix.

The question might arise, as there was a coagulation of blood in the varices, was there not a cachectic thrombosis? While the man is not very robust and presents signs of anæmia, he presents no signs of tubercular lesions of the lungs or peritonæum, or symptoms of marasmus. There are no hæmorrhoids, varicocele or symptoms of arthritis. The pain, the ecchymotic color of the skin, indicate inflammation and a varicose phlebitis.

In the discussion of this case, M. Legroux referred to a case which he had seen the year before, of a woman sixty years of age, who had suffered for years from a fibrous tumor of the uterus, and who presented a varicose development of the abdominal cutaneous vein, the terminal divisions of which joined the mammary veins which were equally dilated. These abdominal varices were the seat of a phlebitis.

MEDICINE.

THE APYRETIC FORM OF TYPHOID FEVER.—M. Brothier (*Jour. de Med. et de Chir. Pratique*) has collected a large number of observations which demonstrate the existence of a dothinerteritis, in which the temperature does not exceed the normal, at least if there be no complications. While this condition is found to exist, there are but few authentic instances; and this form should not be confounded with the ambulatory form of typhoid fever, which is accompanied by an elevation of temperature.

In these cases the symptomatology is not markedly different, with the exception of the absence of fever, from that observed in a light case of typhoid fever. The abdominal symptoms are but little marked, but the nervous phenomena are pronounced—the tendency to vertigo, the cephalalgia, frequently prostration and stupor, slowness of speech, tremulousness of the tongue and lips, the decubitus, pains in the limbs, and the typical facies, all form marked characteristics of the disease. At the end of a few days these symptoms all disappear by degrees, and the disease is supposed to be terminated. But, on the contrary, the intestinal changes are continuing, and from the seventeenth to the twenty-fifth day hæmorrhages or perforations develop themselves, and the autopsies demonstrate that the alterations pass through their three usual phases, in such a manner as that long after all morbid symptoms have disappeared and the patient has commenced to feel hunger, he is exposed to the ordinary complications of the disease. We see produced in such cases peritonitis without perforation,

the sacral bed-sore, and the degeneration of the muscles, notwithstanding the absence of fever.

The cause of this anomaly is probably due to the attenuation of the virus on the one hand, and to the feeble intensity of the local manifestations on the other. But the important point is that of diagnosis, for it admits of preventing grave complications. It can only be established, in the absence of the fever, upon the group of symptoms so commonly present in typhoid fever. The rose spots constitute the most positive of these symptoms; then comes the nervous phenomena, the hypertrophy of the spleen, and the characters of the diarrhoea and the urine. It is important to recognize the fact that the patients must remain in bed, as in the ordinary forms. In this way there is a better chance of avoiding serious complications. But the absence of fever constitutes a difficulty where the diet is concerned, as ordinarily the presence of fever contra-indicates solid food. In this form it is best to abstain from solids for eight days after the disappearance of the rose-colored spots, or, if they be absent, after the disappearance of the other symptoms.—*Arch. Med. Belges.*

THERMIC SIMULATION IN A CASE OF HYSTERIA.—Dr. Du Castel reports to the Société Médicale des Hôpitaux (*Bulletin*) an account of a hospital case where a young woman 21 years of age, who suffered from certain pronounced nervous symptoms of a character to cause the suspicion of a lesion of the cerebrum, caused the falsification of the thermometric record in such a manner as to defy detection and to break several tubes from the elevation of the mercury. The thermometer placed in the vagina and under the axilla would rise to 113° F. in an irregular manner and at all hours of the day. Sometimes the vagina would show a normal temperature, while the axilla would be elevated, and *vice versa*. This of course aroused suspicion, so she was given a new thermometer and left to her own devices, when the mercury rose to over 118° F., and soon the tube was broken. Another reached 168° F.

One of the hospital assistants, M. Espaignet, found that by striking lightly the upper end of the thermometer while in the axilla, it was possible to produce an indefinite rise in the column of mercury. The patient then being watched, was seen to quietly introduce her hand beneath the bed-clothes and heard to tap the thermometer in the vagina. The next day Dr. Du Castel, while taking the temperature in both axillæ, turned away as if by accident for a moment, and on returning to his patient, saw her draw her hand away quickly from the extremity of the thermometer in her right axilla. When the thermometers were withdrawn, the right registered 37.9° C., the left 37.2°.

The patient left the hospital without admitting any fraud on her part, but the doctor was satisfied that this was the mode of committing it, and with such ease as to deceive completely the externes and nurses placed to watch her; she profiting by the slightest opportunities caused from momentary absence.

A NEW METHOD OF TREATMENT OF ACUTE PLEURISY.—Prof. Picot (of Bordeaux), describes his new method of treating acute pleurisy when it has been found necessary to puncture. It has been his custom after thoracentesis to apply immediately a large blister over the region, to prevent, as far as possible, any re-formation of the fluid. But, in order to produce a more powerful revulsion, his assistant, Dr. Cayla, after evacuating the fluid as completely as possible, covers the affected region with cauterized punctures made by the thermocautère. These cauterizations are practised immediately after the evacuation; they are very numerous, but a short distance from each other, and their application is followed by a powerful revulsion over the whole of the thoracic region corresponding to the diseased pleura. This method has been used several times without accident. The patients, men and women, bear it well, and the punctures are made with care that the cauterization shall not include more than half the thickness of the derm.

M. Picot cited in support of his method a number of favorable cases, in all of which there has been no return of the fluid, and a cure was effected in a few days. One case was particularly interesting—it was a case of acute miliary tuberculosis, with a considerable accumulation of fluid on the left side which required thoracentesis; 2,050 grammes of fluid were evacuated, and the cauterization was performed as usual. There was no return of the fluid to be detected by physical signs, and the patient dying some little time after by the progress of the tuberculosis, the autopsy showed that the pleura from which had so recently been extracted a large quantity of fluid, no longer contained any traces of it.

PATHOLOGY.

THE HISTOGENESIS OF TUBERCLES.—According to Professor Baumgarten, of Königsberg in the *Centralblatt für Klinische Medizin* (*Medical Times*), the development of specific tubercles can be studied most easily and accurately in the changes which take place in the iris of albino rabbits after tubercular matter has been introduced into the anterior chamber of the eye. The first stage is the migration of the bacilli from the particles introduced into the iris tissue, which at this period is perfectly healthy. The free bacilli themselves enter the iris, they are not conveyed into it by wandering cells, and when there they multiply and spread in the tissues. On the tenth or eleventh day after inoculation the iris still looks healthy, although bacilli can be found all over it, both in the intercellular substance and in the cells. In those spots where the bacilli begin to group themselves into nests, changes take place which always lead to the production of typical tubercles.

Whilst in their normal condition the fixed cells of the stroma of the iris of albino rabbits have the form of thin plates, which appear if seen edgewise as free oval nuclei attached to the wall of the particular intercellular space under observation; under the influence of the bacilli these cells swell up to large cubic or polygonal masses of protoplasm (the epithelioid cells of tubercles of authors). The fibrillar

intercellular substance becomes compressed and rarified by the pressure of these, and is more and more reduced to that delicate network known as the reticulum of the tubercle. Whether a hyperplasia and multiplication of the fixed connective tissue cells take place as well as this hypertrophy of the individual cells is not certain, but if it occur it must be in so slight a degree as to take only a subordinate place in the formation of tubercles. The giant cells of tubercles must at present be considered as rising from a fusion of several of these epitheloid cells and not from a multiplication of the nuclei of a single cell.

The wandering leucocytes take no part in the formation of these epitheloid tubercles; a tubercle having this structure can be perfectly developed without the aid of single leucocyte, and the few which wander into it in the course of its development perish—they shrink to irregular masses and ultimately break up into small granules. The number of bacilli in the nest which gives rise to one of these epitheloid tubercles in the iris of an albino rabbit is never very great even when the tubercle is completely developed, but the bacilli increase in number from day to day, and after some time an attack of iritis sets in, generally suddenly; there is a rapid dilatation of the blood vessels and numerous leucocytes migrate into the stroma towards the tubercles. If the tubercles are examined at this stage, we find they present the typical structure of a Wagner-Schüppel tubercle, a sharply contoured cellular mass containing no blood-vessels, the centre composed of epitheloid cells and generally one or several giant cells, the periphery prazone more or less wide, composed of lymphoid elements, the whole penetrated by a delicate fibrillar network.

The bacilli in the nest become more and more numerous, and this immigration of leucocytes into the tubercle goes on till the whole mass has the appearance of a small-celled lymphoid structure. The only subsequent changes which can possibly take place in a tubercle after it has reached this lymphoid stage, are those of degeneration and destruction. No lymph cell tubercle has ever been seen to change into an epitheloid or a giant-celled tubercle in the iris of a rabbit. Other studies of the development of tubercles in other parts of the body and other tissues appear to show that tubercles always grow in a similar way, the different appearances depending on the rate at which the tubercles develop and at which the different stages follow one another. The rate of growth varies with the number and vigour of the bacilli; the more rapid the increase in the number of these, the more quickly does the primary epitheloid tubercle change into a lymphoid tubercle, and in very malignant cases the bacilli may multiply so rapidly that the epitheloid stage has such a short duration that the tubercles appear to be developed at once in the lymphoid stage, and consequently break down at a correspondingly rapid rate.

On the other hand, the tubercles may retain their epitheloid and giant-celled structure for a very long time when there are but few bacilli. From these observations we can understand how the pure lymphoid tubercles are the most malignant, and are only found

in the worst cases, the mixed Wagner-Schüppel tubercles in more chronic ones and the almost purely epitheloid forms in cases of tuberculosis of lymph glands, lupus, tubercular disease of joints, etc.

OBSTETRICS AND GYNÆCOLOGY.

THE RELATIONS OF OVULATION AND MENSTRUATION.—Dr. Lawson Tait considers this question in a paper read before the Midland Medical Society (*Medical Times*). His views as expressed in his book on "Diseases of the Ovaries" are, that menstruation has no analogy to the vestrus or rut among the lower animals, and he thinks there is not the slightest foundation for saying that women have stronger sexual desires at the menstrual period than at others. Then comes the question, has the so-called ovarian excitement, alleged to arrive at the ripening of a follicle, anything to do with the process of menstruation?

In answering this Dr. Tait reviews the literature of the subject and concurs strongly with the views of Dr. A. Reeves Jackson as published in an article in the *American Journal of Obstetrics* for October 1876, and concludes that in those cases of double ovarian cystoma, in which menstruation goes on during the growth of the tumor, that process cannot in any way be dependent on the ripening and discharge of ova. To support his views he gives the record of examinations in 49 cases of operations for removal of both ovaries, resting there satisfied that the evidence so far has completely destroyed the ovular theory of menstruation. These cases arrange themselves as follows:

1. Cases, nine in number, where it was evident that menstruation and ovulation were concurrent.
2. Cases of negative proof against the ovulation theory of menstruation, fifteen in number.
3. Cases, twenty-five in number, affording positive evidence against the theory.

In one case where the appendages were removed for menstrual epilepsy, age 23; the operation was performed four days before an expected period; one follicle had just burst (probably did so during the operation) in the right ovary, and another was nearly ready in the left ovary. This would seem to indicate according to the older theory that it might happen that occasionally menstruation should occur twice within a very few days, with a perfectly healthy uterus and ovaries, for in that case and in others it was quite clear that two ova would be discharged within a few days of each other.

Another inconsistency is that the most marked and proper menstruation has been in cases of disease of the tubes, just as the most profuse lachrymation occurs in inflamed eyes; but in these cases, as a rule, not only is there no ripe vesicle to be seen, but the ovaries are generally so disorganized that no vesicles of any kind are visible. These conditions clearly show that the ovaries have little or nothing to do with menstruation, and render it highly probable that the tubes are largely concerned in it.

THE

Journal of the American Medical Association.

PUBLISHED WEEKLY.

THE EDITOR of this JOURNAL would be glad to receive any items of general interest in regard to local events, or matters that it is desirable to call to the attention of the profession. Letters written for publication or containing items of information, should be accompanied by the writer's full name and address, although not necessarily to be published. All communications in regard to editorial work should be addressed to the Editor.

SUBSCRIPTION PRICE, INCLUDING POSTAGE.

PER ANNUM, IN ADVANCE..... \$5.00.

SINGLE COPIES..... 10 CENTS.

Subscriptions may begin at any date. The safest mode of remittance is by bank check or postal money order, drawn to the order of the undersigned. When neither is accessible, remittances may be made at the risk of the publishers, by forwarding in REGISTERED letters.

Address

JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION,
No. 65 RANDOLPH STREET,
CHICAGO, ILLINOIS

SATURDAY, JULY 5, 1884.

EPIDEMIC CHOLERA.—The recent outbreak of cholera in Toulon of which notice was given in the last JOURNAL, has been so sudden and severe as not only to create a panic among the citizens at home, but also to awaken intense solicitude everywhere, lest the scourge should defy all sanitary restraints, and again traverse Europe and America as in former times.

From the most reliable advices at our command we gather the following facts:

The presence of cholera in Toulon was not generally known until June 24. On the 14th of June one death had occurred, on the 19th, one; 20th, two; 21st, three; 22d, thirteen; 23d, five, and on the 24th, twelve.

It is stated that the greater number of cases are of a mild character, about equally prevalent among civilians and the military, chiefly among the aged and the young.

At a meeting of physicians of Toulon, held on the 28th inst., it was the opinion of a majority of them that the epidemic was Asiatic, and that all measures known to sanitary science for its control should be at once adopted, and vigorously executed.

On June 24 cholera made its appearance at Marseilles, a child aged 13 months, and a youth of 17, dying from the disease. The boy had contracted the disease while at school in Toulon. The American Consul has been instructed by our Government to cable the daily progress of the disease. Our latest reports state that on June 25 there were ten new cases reported at Toulon. Roman advices note the arrival of one cholera patient direct from Toulon, who was immediately isolated from the public.

With reference to quarantine efforts we learn that all the roads and mountain passes of France are being carefully guarded to prevent the passage of persons afflicted with cholera. Austria is also moving in the matter, and proposes at once to quarantine against vessels arriving from the Western Mediterranean ports. Vessels arriving at Trieste are placed in quarantine ten days, if the crews are in healthy condition, and for twenty days if there is any suspicion of sickness. With reference to the early and thorough sanitization of all the great cities and thoroughfares, both in Europe and America, we enter a most emphatic appeal. The work can not be too thoroughly done, nor too soon. It becomes all organizations and individuals charged with the conservation of the public health to use the utmost diligence to perfect the most approved methods of prevention, and to have their plans fully and wisely matured for the disposition and treatment of patients, whenever and wherever the disease may make its appearance.

It is unwise to create any unnecessary alarm, and we sincerely hope the disease may be controlled to its present limits, but it becomes the medical profession everywhere to exert itself wisely and vigorously to secure to the people the utmost exemption possible from cholera invasion.

Later: Since the above was written, despatches to July 1 show a continuance of cholera both at Toulon and Marseilles, and its extension to the suburbs of the former city. At Daluzzo, in Italy, one case is reported which proved speedily fatal. It was in the person of a workman recently from Lyons, where several cases have also occurred. If the disease follows the course of nearly all the former epidemics, it will extend over the greater part of western Europe during July and August, but will not develop in this country until the summer of 1885. There are already indications, however, that the ratio of deaths from the diarrheal or choleraic affections will be unusually high during the present summer, especially in most of our cities. The deaths in Chicago for the week ending June 28 were 29 more than during the corresponding week of last year. The utmost attention should be given to the maintenance of the best sanitary conditions possible, both by municipal authorities and individual citizens. Such attention is as important in its bearing on the prevalence of the ordinary diseases of every year, as upon that of the most dreaded epidemic.

YELLOW FEVER.—This disease continues to prevail in Havana and other places bordering upon the Gulf, and extends into Guaymas in Mexico; thereby keeping the sanitary authorities in our Southwestern States on the alert.

SUBSCRIBERS.—A few of those who subscribed for the JOURNAL by signing and returning the first pledge of support, and who have been receiving the JOURNAL.

NAL regularly all the past year, have not yet paid their subscriptions. Bills have been sent to all such, and we trust the amount will be remitted to this office without delay. All members of the Association should remember to remit their dues to the Treasurer, R. J. Duglison, M.D., Lock Box 1274, Philadelphia, Pa., early, and not wait, as many did last year, until near the close of the JOURNAL year, and then expect to be supplied with all back numbers.

LITERARY HONORS.—At the recent annual meeting of the Faculty and Trustees of the Northwestern University, the honorary degree of Master of Arts was conferred upon Dr. Ralph N. Isham; and the degree of LL.D. was conferred by Dickenson College at its 101st anniversary Commencement upon Dr. Samuel J. Jones, both well-known members of the profession in this city.

TO NEW MEMBERS OF THE ASSOCIATION.—We are dependent upon the Treasurer for the names and address of all new members who first joined the Association in Washington. The names of most of those who reside in the larger cities are not accompanied by any street or number, in consequence of which many of the copies of the JOURNAL are delayed in the delivery, and some go into the general delivery department, and not being called for, they are lost, while those for whom they were designed are blaming us for not sending the JOURNAL. The fault is not with the Treasurer, but in the failure of each member when registering at the meeting, to add the street and number to his address. Let all who find their address faulty immediately inform us by postal card, and this difficulty will be obviated.

SOCIETY PROCEEDINGS.

OBSTETRICAL SOCIETY OF PHILADELPHIA.

Special meeting, June 6, 1884. Vice-President Dr. B. F. Baer, in the chair.

Dr. Wm. Goodell exhibited specimens of
PYO-SALPINX AND HYDRO-SALPINX.

In the former case the lady was unmarried, and had suffered from pelvic pains and menorrhagia for several years. Last autumn a tumor was discovered by her physician, who deemed it a fibroid of the womb. Early this year her sufferings became so great that she took to her bed. Very large doses of morphia were needed, and septic symptoms now set in. After she had been in bed for several weeks, Dr. Goodell was called in to see her. The tenderness of the abdomen was now so great that the examination was made under ether. Even then the diagnosis was obscure because she flinched and her recti muscles became tense whenever the abdominal wall was pressed upon. A cyst was discovered, but of what nature it was impossible to determine. Dr. Goodell operated on her at his private hospital. The womb was studied with small fibroid nodules, posteriorly it had an outgrowth as large as a small egg. Closely adherent to the womb, to the pelvic fascia and to the intestines,

was a thick-walled cyst of the left ovary, as large as the largest orange. The corresponding oviduct was very thick and enlarged to the size of a small sausage. It and the cyst were filled with a very dark purulent fluid, although there was no communication between them. The lower end of the cyst had become necrosed, and was so thinned out that it would very soon have given way at that point. On account of the presence of fibroids in the womb, the right ovary was also removed. Attached to the fimbriae of the oviduct were three very beautiful pedunculated vesicles; while two others not yet pedunculated lay in the stroma of the broad ligament. The recovery of the lady was uninterrupted.

In the case of hydro-salpinx, the patient was a widow aged 37, who had been sent to him in order to have her ovaries removed. Severe pains began a week before the menstrual flow, culminating during the flow and continuing one week longer, then fading gradually away. For three weeks out of every month she was confined more or less to the recumbent posture, and wholly so during the menstrual week. A tear of the cervix and one of the perinæum had been well repaired by two surgeons, but with no improvement. Dr. Goodell wished her at first to try the rest treatment with massage, electricity and graded muscular movements, for he had repeatedly cured cases of this kind through such a mode of treatment. She was, however, too poor to take this treatment privately, and was therefore urgent to have her ovaries removed. The operation was performed fifteen days ago, and she is now doing very well indeed. The ovaries as exhibited were much enlarged, and showed marked follicular degeneration. From this condition Dr. Goodell thought that nothing short of the operation would have cured her. Attached to one oviduct was a delicate vesicle with a thread-like stem of over an inch in length. In view of the frequency with which they are found, he could not but think that these vesicles played some role in the economy, and that they had sometimes a pathological bearing. He had on several occasions met with small post-uterine cysts which burst either spontaneously or under the pressure of an ordinary vaginal examination. Taking advantage of this fact, he had quite recently burst one designedly by bi-manual pressure. Such delicate cysts, and also those very movable ones which remained small without increase in bulk, he was disposed to attribute to these vesicles. After bursting these cysts sometimes refill. One he had known to burst and refill at least six times before it disappeared. New small ovarian cysts had, in his experience, thick walls, and, further, they rarely remain small any length of time. Dermoid cysts, on the other hand, often remain stationary for years, but they were generally not very movable, and they also had thick walls.

Dr. Albert H. Smith had found these cases of pyosalpinx very difficult of diagnosis. He had been present at an operation by Knowsley Thornton upon a case in which the lesion was double and both tubes and ovaries were removed. Rupture had occurred previously, and had been followed by peritonitis. The patient recovered.

Dr. B. F. Baer inquired if Dr. Goodell would recommend rupture of cysts arising from the hydatids of morgagni.

Dr. Goodell would consider it good surgery for the purpose of preventing the further growth of the cyst. He had always found the fluid in small cysts to be unirritating.

Dr. Albert H. Smith remarked that Schroeder holds that the fluid of an ovarian cyst is not noxious to the peritonæum. He makes no effort to protect the peritoneal cavity from its ingress during an operation, and yet his statistics show a remarkable success.

In response to a question by Dr. C. Meigs Wilson, Dr. Goodell stated that the dressing of the wound after the operation was glycerole of carbolic acid with the Lister gauze.

Dr. Goodell also gave the following history of a case of hysterectomy. The woman was unmarried, aged 47. Her monthly fluxes began to be free in 1867. A year ago they became so exhausting that she could not pursue her trade as a seamstress. On April 30 she consulted Dr. Goodell, who found the whole abdomen filled with multiple fibroids of the womb. The cervix had disappeared and the os uteri lay so high up that it was not possible to introduce the sound. The operation was performed at the Hospital of the University of Pennsylvania, on May 22, on the same day with the preceding case. One outgrowth as large as the two fists contained a cavity filled with cheesy matter, and was so adherent to the abdominal wall and intestines as to need the knife for its release. It was possibly the right ovary, but he was by no means certain. Koeberle's wire-clamp was passed around what corresponded to the neck of the womb, but it was as large as his arm above the elbow. The woman's recovery thus far has been uninterrupted. The temperature reached 100° but once. The clamp fell off on the 16th day, leaving a very deep funnel-shaped pit. He had intended to exhibit the specimen, but it was too bulky to carry and also had become quite offensive. In this case had he been able to reach the ovaries or to have discovered them he would have removed them in preference to performing hysterectomy; but the firm adhesions prevented the rotation or the lifting up of the tumor, hence the ovaries were inaccessible. Sometimes even when the uterine fibroid can be lifted out of the wound and the ovaries reached, these organs are so embedded in the fibroid, or so drawn out in ribbon-form on the surface of the tumor as to make their complete removal impossible. When, however, the ovaries can be removed with safety, the operation is a most promising one, as he could attest from several most successful cases.

Dr. W. T. Taylor reported the following case of Partial Placenta Previa. Mrs. S., an English woman, aged 46 years, the mother of ten children, came to see me in December, 1883, in consequence of abdominal pains, headache and vertigo, with a suppression of her menses which she attributed to a "change of life," as she had been irregular for a year past. She also had numbness with tingling in the hands and feet and had not been so affected in any former

pregnancy. Consequently she would not believe in her condition until some weeks later when she quickened. In the month of February last she had enlargement of the veins of the legs with edema of the feet and ankles, for which she took occasional doses of potassium bromide with a solution of cream of tartar (3i to water one pint) to be taken freely. By this treatment she was temporarily relieved.

On March 27, she had abdominal pains and a profuse hæmorrhage which saturated her clothing and greatly alarmed her. On examination I found the os-uteri high up and slightly open. Although the hæmorrhage diminished, yet the pains would recur at intervals, and I fully expected labor would soon begin. Under the use of equal parts of wine of ergot and solution of sulphate of morphia she began to get easier, and in a few days was out of bed and able to resume her household duties; feeling more comfortable, as the enlarged veins were smaller, her feet and ankles had diminished in size and the headache gone entirely. I told her that nature had come to her relief and bled her without my ordering it.

Feeling satisfied that this was a case of placenta previa and that there was no immediate danger, I concluded the most prudent course was to let nature alone and wait until labor began. She had no more trouble until May 10, when she passed a large clot of blood and complained of slight pains in the abdomen; these occurred occasionally for two days, when the membranes ruptured and a sudden gush of water followed by a flow of blood indicated that labor had begun. On examination, I discovered within the os a spongy, ragged, bleeding mass of tissue, which was recognized as the placenta; with each pain the flow of blood increased as the cervix dilated. Sweeping my index finger around within the mouth of the womb, as far as I could reach, to detach the placenta from the uterine walls and assist the first stage of labor, I felt the fetal head beyond.

To arrest the bleeding, which, if it continued, would exhaust the mother and destroy the child, I plugged the vagina completely with strips of old muslin well saturated with lard and waited patiently for the os to dilate and the head to advance, giving at the same time occasional doses of quinine and wine of ergot as a tonic and stimulant. In about an hour the advancing head had expelled a part of my tampon, and on removing the remainder, I found that the bleeding had ceased and the vertex was presenting in the left occipito-posterior position. Auscultation revealed a feeble fetal circulation, but as the pelvis was roomy and my patient somewhat exhausted, I gave her freely of milk-punch until her pulse became stronger, which it did in half an hour, when as the head had ceased to advance I applied the forceps and delivered her of a medium-sized girl, which in a few minutes began to cry with some vigor, contrary to my expectations, for I had told them it would probably be dead. Its vitality had been preserved by the adhering part of the placenta, which then came away quite easily. A teaspoonful of fluid extract of ergot contracted the womb firmly. My patient was weak for several days, but under the use

of tonics with nourishing food she soon recovered her usual strength.

Dr. A. H. Smith remarked that this case being partial and without profuse hæmorrhage could have been best carried through by rupturing the membranes and bringing down the head, which would have stopped the hæmorrhage as soon as it engaged in the superior strait. Dr. Smith asked the question, Under what circumstances are we warranted in interfering? If the hæmorrhage is alarming and the patient exhausted, she is in a poor condition to bear interference, and on the other hand we have no right to interfere if there is no pain or hæmorrhage. To interfere by manipulation is very dangerous unless the uterine contractions are rapid and effective after labor once begins. The position of the child should be carefully and accurately determined by external manipulation before interference becomes necessary, so as to know where to seek the feet if turning becomes imperative. When the placenta previa is complete, dilatation of the os causes a terrific hæmorrhage, the blood streams from the patient like water from a hydrant or a small fire-plug and death comes very quickly. Only perfect knowledge of the condition of things and the position of the child will enable the physician to avert the doom. Now as to the tampon. I would not use it. It hides the hæmorrhage which may be going on protusely behind it, as was so vividly described by Dr. Goodell in his paper on Concealed Accidental Hæmorrhage of the Gravid Uterus, in Vol. 2, *American Journal of Obstetrics*, in which he showed that the woman might bleed to death without one drop of blood escaping externally. The tampon conceals the hæmorrhage without necessarily preventing it, and while it remains in place one hand of the physician should be constantly on the patient's pulse to note instantly any failure of the heart; while the other should be on her abdomen to note any changes in size of the uterus or position of the fetus. In Dr. Taylor's case the treatment was beyond criticism because the result has been happy.

Dr. Goodell agrees with Dr. Smith that placenta previa is the most formidable complication in obstetrics. No general rule can be made applicable to the treatment of all cases. In partial ones the membranes should be ruptured and the head brought down. It must always be borne in mind that in these cases the implantation of the placenta has caused increased vascularity and thickness of the cervical walls, they are easily ruptured, and if torn, bleed profusely. There is greater danger of septicæmia from absorption of decomposing lochial discharges when passing over this surface if it is torn. He well remembered one case which he attended years ago in consultation with Dr. Augustin Fish, since deceased, in which, in consequence of what he now considers undue haste, lacerations of the cervix occurred and, although the labor terminated happily, septicæmia set in a few days later and resulted fatally. It would have been better in that case to tampon. When the placenta is not central there is very little danger, there is some. The tampon may be used, but the pulse must be constantly watched and frequent ab-

dominal palpation should be made. He had been struck with the method practiced by Dr. Ellwood Wilson more than twenty years ago. It consisted in gentle digital dilatation of the os, introducing first one finger, then two, and so on; as soon as sufficient space was obtained he gave ergot, made podalic version and delivered. Very few practitioners advise that method. Dr. Goodell had not met with many cases, and the one spoken of above was the only fatal one. He has used Barnes' dilators, taxis, strength and courage and has tried to adapt his treatment to the indications of each particular case.

Dr. W. H. Parish thought the tampon was not used as frequently now as it was a few years ago, either in the form of Barnes' dilators or the vaginal plugs. Under similar circumstances he would probably do as Dr. Taylor did. Partial placenta previa is not very dangerous, but in complete the hæmorrhage is excessive. In one case he had tamponed for several hours when, the os being dilated he etherized and readily delivered a living child. The mother was in imminent danger of death from hæmorrhage. The abdominal aorta was compressed, ice was used to the cervix, but without success. The hæmorrhage was controlled by the application of a cloth, wet with Monsel's solution to the denuded cervical and uterine surface.

Dr. Taylor has used the tampon in several cases of partial placenta previa and in numerous cases of abortion, and has never yet had bleeding to go on behind it. The line of treatment practiced in this case has always proved satisfactory as regards results.

Dr. Goodell remarked that the womb at term was large, and concealed hæmorrhage might be free enough to cause death, but there was no such danger in an abortion at two or three months.

Dr. B. F. Baer exhibited a specimen of sub-mucous and interstitial uterine fibroid, and read the following report of the case: Mrs. G., aged 51 years, married, four children. Her first child was born after she had reached her 30th year, and the last one when she was 38, thirteen years ago. Her labors were very severe. Several years ago she began to lose large quantities of blood with her catamenial periods, and to suffer severely with labor-like pains. This continued with increasing quantity and severity until the cause was removed. Two years ago she had so great a flooding, that it was thought for weeks she would succumb. She gradually recovered from the immediate effects of the hæmorrhage, but has been losing flesh and strength ever since. Moreover, as she would recover a sufficient amount of strength to support it, a severe metrorrhagia would recur. Recently she had rarely been free from bleeding and a profuse non-foetid watery discharge.

At the request of my friend, Dr. Fred. C. Seiberling, the family physician, I met him at the home of the patient, at New Tripoli, Lehigh county, Penn., when I saw her for the first time. She had a sallow, jaundiced, and anæmic-looking surface, was somewhat emaciated, but did not have the characteristic cachectic appearance of carcinoma. Her pulse was 120, and not strong. As she was too weak and excited to permit of a thorough examination without it,

ether was at once administered by Dr. J. W. Seiberling, when the following condition was revealed by physical exploration: The upper portion of the vagina was occupied and distended by the cervix uteri, which was stretched and expanded over a firm, rounded mass, which presented at the os; the latter was dilated to about the size of a silver dollar, and the body which presented resembled very much in size and shape the head of a seven-months' foetus. Bimanual examination showed the uterus to be as large as at the end of the sixth month of gestation, and rather symmetrically developed, but it was quite firm and resisting, if not hard. The sound could not be introduced for the following reason: On the right side the tumor was firmly attached to the cervical wall all the way to the external os, and on the left almost to the same extent, though here I was able to pass the sound and finger to a depth of about an inch. I confirmed Dr. Seiberling's diagnosis of sub-mucous fibroid, and thought from the size of the uterine globe, as outlined by abdominal palpation, that the tumor had also a deep interstitial attachment or *nidus*. I advised an attempt at enucleation of the growth as the only means of saving the life of the patient, and with the assistance of Drs. F. C. Seiberling and W. K. Kistler I proceeded with the operation. I was at a loss, at first, to explain the close connection which the tumor had with the cervical walls, a connection so intimate that it seemed in part to grow from that organ, but the history of the growth of the tumor was against that idea; the patient had been under close observation at least four years, during most of which time the cervix was free from disease. There had been no evidence of abnormal growth in the cervix until six months before the date of operation; about that time the tumor was detached at the internal os. I thought that the close connection with the cervical wall might have been due to adhesive inflammation, and acting on that theory I began my operation by trying to separate the adhesions, but I soon found that I had made a mistake, and that I was dissecting up the tissues of the cervical wall. I then concluded it must be the capsule of the tumor, which had been stripped off by the growth as it was made to advance toward the external os by contractions of the uterus, and this view was confirmed, for when I had removed the tumor the capsule hung as a curtain from the edge of the external os. After vainly endeavoring to deliver the tumor by traction, I cut directly into it with scissors, dividing the mass into two portions. I then introduced Thomas's spoon-saw into the cavity, and with it and my fingers I tore the growth from its nest in the fundus and sides of the uterus, removing it piecemeal. Very little hemorrhage occurred during the operation, which occupied fully an hour and a half. After trimming the ragged edges of the capsule from around the os, I injected the cavity with vinegar and packed it full of sponges saturated with the same excellent antiseptic and hemostatic. A gr. ss. morphia suppository was placed in the rectum, the patient removed to her bed and surrounded by bottles of hot water. She reacted nicely, and in the evening 10 grains of quinine were given. On the next day the sponges were removed,

the cavity irrigated with carbolyzed water and re-packed as before. Under the care of Dr. Seiberling the patient has recovered without an untoward symptom. The tumor probably weighed three pounds.

W. H. H. GITHENS, Secretary.

STATE MEDICINE.

The following law relating to Medical Examiners and Coroners was recently enacted by the General Assembly of Rhode Island:

CHAPTER 420.

An Act relating to Medical Examiners and Coroners.

(Passed April 30, 1884.)

It is enacted by the General Assembly as follows:

SECTION I. The Governor shall appoint, in each county, able and discreet men, learned in the science of medicine, to be medical examiners in such county.

SEC. 2. The number of medical examiners appointed, as provided in the preceding section, shall be as follows:

For the County of Washington, five Examiners, one in each of the five following districts, viz.: District one composed of the town of Westerly; District two of the town of South Kingstown; District three of the towns of Hopkinton and Richmond; District four of the towns of North Kingstown and Exeter; District five of the town of Charlestown. For the County of Kent two Examiners, one in each of the two following districts, viz.: District one composed of the towns of West Greenwich and Coventry; District two of the towns of East Greenwich and Warwick. For the County of Providence, eleven Examiners, one in each of the first nine following districts; and in District ten two Examiners, viz.: District one composed of the towns of Scituate and Foster; District two of the towns of Cranston and Johnston; District three of the town of Glocester; District four of the towns of Smithfield and North Providence; District five of the towns of Burrillville and North Smithfield; District six of the town of Woonsocket; District seven of the town of Cumberland; District eight of the towns of Pawtucket and Lincoln; District nine of the town of East Providence; District ten of the city of Providence. For the County of Bristol, two Examiners, one in each of the following districts, viz.: District one composed of the towns of Barrington and Warren, and District two of the town of Bristol. For the County of Newport four Examiners, one in each of the two first districts and two in District three, viz.: District one composed of the towns of Tiverton and Little Compton; District two of the town of New Shoreham; District three of the city of Newport and the towns of Portsmouth, Middletown, and Jamestown.

SEC. 3. If either of the Medical Examiners shall, at any time, from any cause, be unable to perform the duties of his said office, or shall be deemed by the Attorney-General for any cause disqualified therefor, a Medical Examiner from an adjoining district may be called upon to perform them.

SEC. 4. Every Medical Examiner shall hold his office for a term of six years, and until another is appointed and qualified to act in his place, unless sooner removed by the appointment of some other person to fill his place.

SEC. 5. Every Medical Examiner shall within thirty days after his appointment, and before entering upon the duties of his office, give bond with surety to, and to the satisfaction of, the General Treasurer in the sum of one thousand dollars, for the faithful performance of his duties.

SEC. 6. If the condition of any such bond be broken, to the injury of any person, actions may be brought upon such bond as upon the official bonds of sheriffs.

SEC. 7. Medical Examiners shall make examinations as hereinafter provided, upon bodies of such persons only as are supposed to have come to their death by violence.

SEC. 8. When a Medical Examiner has notice that there has been found, or is lying within his district the body of a person who is supposed to have come to his death by violence, he shall forthwith repair to the place where such body lies, and take charge of the same, and if, on view thereof and personal inquiry into the cause and manner of the death, he deems a further examination necessary, he shall, upon being thereto authorized, in writing, by the Attorney-General, or by the Mayor of the City or President of the Town Council of the town where such body lies, make an autopsy in the presence of two or more discreet persons as witnesses, and shall then and there reduce, or cause to be reduced, to writing, every fact and circumstance tending to show the condition of the body and the cause and manner of death, together with the names and addresses of said witnesses, which record he shall subscribe. Before making such autopsy he shall call the attention of the witnesses to the position and appearance of the body.

SEC. 9. Should the Medical Examiner deem it advisable to have present a physician as one of the witnesses, as aforesaid, such physician shall also subscribe the record made by the Medical Examiner, and for such service he shall receive a compensation of five dollars.

SEC. 10. Town councils shall elect a suitable person to act as coroner for their respective towns, to hold his office for three years and until another is elected and qualified to act in his place, unless sooner removed by the election of some other person to fill his place.

SEC. 11. The coroners so elected shall have exclusive jurisdiction as coroners in their respective towns.

SEC. 12. The coronor shall appoint in writing, under his hand and seal, one or more discreet persons to act as his deputy, in case of his absence or inability to act, who shall have all the powers of a coroner, and be subject to like pains and penalties for malfeasance in office; and the coroner shall file a copy of the appointment in the town clerk's office of his town.

SEC. 13. The coroner may suspend or discharge

a deputy. The suspension or discharge of a deputy shall be in writing, addressed to the deputy; and the coroner shall forthwith file a duplicate thereof in the town clerk's office of his town.

SEC. 14. Every coroner and deputy coroner shall, before entering upon the duties of his office, take the engagement prescribed in section 4 of chapter 23 of the Public Statutes.

SEC. 15. Whenever the coroner has notice that there is in his town any person who has been injured by the criminal act, omission or carelessness of another, and that said person believes that his death is impending from any such injury, said coroner may take the statement of such person concerning the manner in which and the person by whom such injury was inflicted, and the statement so taken shall be reduced to writing, and if practicable, in the presence of the injured person.

SEC. 16. If, upon such view, personal inquiry, or autopsy, the medical examiner is of the opinion that the death was caused by the act or neglect of some person other than the deceased, he shall at once notify the Attorney-General and coroner of the town where the body was found, or in which it lies, and shall file a duly attested copy of the record of his autopsy or view with the said coroner and a like copy with the Attorney-General; and shall, in all cases, certify to the officer having the custody of the records of deaths in the town in which the deceased came to his death, the name and residence of the person deceased, if known, or, when the name and residence cannot be ascertained, a description of the deceased, as full as possibly may be, for identification, together with the cause and manner by and in which he came to his death.

SEC. 17. The coroner shall thereupon hold an inquest, which may be private, in which case any or all persons, other than those required to be present by the provisions of this act, may be excluded from the place where such inquest is held; and such coroner may also direct the witnesses to be kept separate so that they cannot converse with each other until they have been examined. The Attorney-General, or some person designated by him, may attend the inquest and examine all witnesses: and the coroner shall cause the testimony to be reduced to writing, and signed by the witnesses. The Attorney-General may, if he deem it necessary or expedient, direct an inquest to be held in the case of any casualty from which the death of a person results.

SEC. 18. The coroner may issue summons for witnesses, returnable before him. The persons served with such process shall be allowed the same fees, their attendance may be enforced in the same manner, and they shall be subject to the same penalties as if served with a summons in behalf of the State in a criminal prosecution pending before a justice court.

SEC. 19. The coroner shall, after hearing the testimony, draw up and sign a report, in which he shall find and certify when, where and by what means the person deceased came to his death; his name, if known, and all material circumstances attending his death; and if it appears that his death resulted wholly or in part from the unlawful act of any other

person he shall further state the name of such person, if known to him, and he shall file such report, and the testimony by him taken, together with a copy of the record of the autopsy or view, in the office of the Clerk of the Court wherein an indictment for the offence may be found.

SEC. 20. The coroner shall bind such witnesses as he deems necessary, or as the Attorney General may designate, by recognizance in a reasonable sum, with sufficient surety, to personally appear at such time as the coroner may designate, at the Justice Court of the town wherein the inquest is held, and not depart therefrom until discharged by said Court; and if any such witness shall refuse to recognize as aforesaid, the coroner shall commit such witness to the jail in the same county, there to remain until he shall so recognize or be otherwise discharged according to law.

SEC. 21. If the report of the coroner shall state that the death was caused by the unlawful act or by the gross carelessness of any other person, and by whose act the same was committed, he shall immediately make a complaint thereof against the person accused, in writing and on oath, to the Trial Justice or Clerk of a Justice Court in the town where the offence was committed, to the intent that the person killing or being in any way criminally instrumental to the death, may be apprehended; but nothing herein contained shall be so construed as to prevent complaint being made at any time before the finding of the report. And the coroner shall forthwith, in writing, notify the Attorney-General of the complaint aforesaid, that he may appear by himself or some person appointed by him, at the examination, and prosecute the complaint in behalf of the State.

SEC. 22. If a medical examiner reports that a death was not caused by the act or neglect of some person other than the deceased, and the Attorney-General is of a contrary opinion, the Attorney-General may, notwithstanding such report, direct an inquest to be held in accordance with the provisions of this act, at which inquest he, or some other person designated by him, shall examine all the witnesses.

SEC. 23. The medical examiner may, if he deem it necessary, employ a chemist to aid in the examination of the body, or of substances supposed to have caused or contributed to the death, and such chemist shall be entitled to such compensation for his services as the medical examiner certifies to be just and reasonable, the same being audited and allowed in the manner hereinafter provided.

SEC. 24. When a medical examiner views or makes an examination of the dead body of a stranger, he shall cause the body to be decently buried, and if he certifies that he has made careful inquiry, and that to the best of his knowledge and belief the person found dead is a stranger, having no settlement in any town of the State, his fees, with the actual expense of burial, shall be paid from the general treasury. In all other cases the expense of the burial shall be first paid by the town wherein the body is found, and such town may recover the money so paid from the town where such person last had a settlement. Provided, however, that the General Treasurer or any town ultimately paying any such

burial expenses shall have the right to recover such burial expenses from the estate of the deceased person.

SEC. 25. When services are rendered in bringing to land the dead body of a person found in any of the harbors, rivers or waters of the State, the Medical Examiner may allow such compensation for such services as he deems reasonable; but this provision shall not entitle any person to compensation for services rendered in searching for a dead body.

SEC. 26. In all cases arising under the provisions of this act, the Medical Examiner shall take charge of any money or other personal property of the deceased, found upon or near the body, and shall deliver the same to the person entitled to its custody or possession, or if not claimed by such person within sixty days, then to an administrator, to be administered upon according to law.

SEC. 27. A Medical Examiner who fraudulently neglects or refuses to deliver any such property within three days after demand upon him therefor, shall be imprisoned not exceeding two years or be fined not exceeding five hundred dollars.

SEC. 28. The fees of coroners shall, for the services specified in this act, be as follows, namely: For receiving and filing a duly attested copy of the record of an autopsy, fifty cents; for every page of two hundred words of written testimony, thirty cents; for each day's attendance in holding the inquest, five dollars; for the recognizance of witnesses, thirty-five cents; and for drawing up and filing a report in court, five dollars. Said fees having been audited by the State Auditor upon certificate of the Attorney General, shall be paid by the General Treasurer.

SEC. 29. Each medical examiner shall receive fees as follows: For a view without an autopsy, four dollars; for a view and an autopsy, thirty dollars; and for travel at the rate of ten cents a mile to the place of view. He shall also have power, in case of an autopsy, to employ a clerk, at an expense not exceeding three dollars per day for each day's actual service.

SEC. 30. Every medical examiner shall return an account of the expenses of each view or autopsy, including his fees, to the State Auditor, and shall annex to his return the written authority under which the autopsy was made. The State Auditor shall audit such account and certify to the General Treasurer what items in such account are deemed just and reasonable, and such items shall be paid by said treasurer to the persons entitled to receive the same.

SEC. 31. Chapter 250 of the Public Statutes, entitled "Of Coroners and their Inquests," and all acts and parts of acts inconsistent herewith, are hereby repealed.

SEC. 32. This act shall take effect on the first day* of July, A. D. 1884, provided that so much thereof as relates to the appointment and qualification of medical examiners shall take effect immediately.

I certify the foregoing to be true copies.

[Witness.]

JOSHUA M. ADDEMAN,
Secretary of State.

BOOK REVIEWS.

THE KINGDOMS OF NATURE, OR LIFE AND ORGANIZATION FROM THE ELEMENTS TO MAN. By RANSOM DEXTER A.M., MD., LL.D. Published by the Tipton Publishing Co., Chicago.

The object of this book, the author states, is to present intelligibly to the average reader the leading facts of Natural History in the most natural order possible, "so that he who runs may read something of the laws or rules of action established by the Creator for the government and conservation of natural objects throughout the wide domain of animal existence."

The facts presented and the order of their presentation may be briefly described as follows:

In the first chapter the author asks "what is life," and describes in a general way the prominent and most universal facts of physiology. The Vegetable Kingdom is described, beginning with the lowest forms of life, and extending chapter by chapter to the highest. In the same way the Animal Kingdom is reviewed. Not only are the anatomical characteristics given but also many of the physiological peculiarities and habits common to whole groups.

That which even the most casual observer of the book will notice with pleasure and commendation is the handsome appearance of the volume. It is well bound, printed on good paper and finely illustrated with nearly four hundred engravings which are well selected. Two of the full page cuts are colored. In addition to the customary table of contents and index there is a glossary of technical words. The work is highly creditable to both author and publisher, and deserving an extensive patronage from the reading public.

MISCELLANEOUS.

We cheerfully call attention to the following circular, and commend the proposition as a fitting mode of commemorating the honored dead.—[Ed.]

THE S. D. GROSS PROFESSORSHIP OF PATHOLOGICAL ANATOMY.—American surgery has had no better exponent than Samuel D. Gross; none so honored abroad and at home by institutions of learning; none more revered by his associates and his pupils. His long and brilliant professional career deserves the perpetuation of his name in close association with medical tuition.

In furtherance of this object, the Alumni Association of Jefferson Medical College has inaugurated a movement to secure, in some medical school, the endowment of a Memorial Professorship, to be designated The S. D. Gross Professorship of Pathological Anatomy.

The profession at large, the personal friends of the late Professor Gross, and others interested in elevating the standard of medical education, are cordially

invited by the undersigned to participate in this graceful recognition of conduct and service which have largely helped to establish the high standard of excellence to which surgery has attained throughout the United States, and served so much to dignify the repute of American Medicine.

Contributions may be sent to Dr. R. I. Dunglison, Treasurer, lock box 1274, Philadelphia, P. O., and will be acknowledged in the columns of the "*Medical News*" of Philadelphia.

D. HAYES AGNEW, M. D., *Chairman.*

J. M. BARTON, M. D., *Secretary,*
1344 Spruce Street, Phila.

OFFICIAL NOTICE.

ANNUAL DUES from members of the Association—*Five Dollars* per annum—are payable directly to the Treasurer. Such payment entitles them to receive the JOURNAL of the Association for one year.

SUBSCRIPTIONS TO THE JOURNAL from those who are not members should be forwarded to the office of publication, Chicago.

BACK VOLUMES OF THE TRANSACTIONS may be procured, at reduced rates, by addressing the Treasurer.

THE INDEX to the 33 Volumes of Transactions will be forwarded, postpaid, on receipt of *One Dollar* by the Treasurer.

According to a resolution passed May 9, 1884, at the Washington meeting, continuous payment of Annual Dues is required, to retain permanent membership.

RICHARD J. DUNGLISON, M.D.,
Treasurer.

Lock Box 1274, Philadelphia, Pa.

LIST OF OFFICIAL CHANGES IN THE MEDICAL CORPS OF THE NAVY, FOR THE WEEK ENDING JUNE 28, 1884.

Surgeon J. S. Knight, placed on retired list.

P. A. Surgeon R. Whiting, detached from U. S. S. "Vermont," ordered to Marine Rendezvous, N. Y.

Surgeon H. J. Babin, detached from Marine Rendezvous, N. Y., ordered to U. S. S. "Minnesota."

Surgeon H. M. Wells, ordered for examination preliminary to promotion.

P. A. Surgeon G. P. Lumsden, detached from U. S. S. "Pensacola," and placed on waiting orders.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT UNITED STATES ARMY, FROM JUNE 21, 1884, TO JUNE 27, 1884.

Magruder, D. L., Lieut.-Colonel and Surgeon, granted leave of absence for one month. (Par. 7, S. O. 143, A. G. O., June 20, 1884.)

Clements, Bennett A., Major and Surgeon, ordered to relieve Major Jos. P. Wright, Surgeon of his duties as attending surgeon at the Leavenworth Military Prison, Fort Leavenworth, Kan. Major Wright on being relieved, ordered to report to the Commanding-General, Department of Texas, for assignment to duty. (Par. 7, S. O. 144, A. G. O., June 21, 1884.)

OFFICERS OF
THE AMERICAN MEDICAL ASSOCIATION
 AND OF ITS SEVERAL SECTIONS, 1884-5.

PRESIDENT.

H. F. CAMPBELL, of Augusta, Georgia.

FIRST VICE-PRESIDENT.

J. S. Lynch, of Maryland.

THIRD VICE-PRESIDENT.

J. W. Parsons, of New Hampshire.

PERMANENT SECRETARY.

Wm. B. Atkinson, 1400 Pine St., Philadelphia.

SECOND VICE-PRESIDENT.

S. D. Mercer, of Nebraska.

FOURTH VICE-PRESIDENT.

H. C. Ghent, of Texas.

TREASURER.R. J. Dunglison, ^{Lock Box} 1271, P. O. Philadelphia.**LIBRARIAN.**

C. H. A. Kleinschmidt, Washington, D. C.

Place of meeting, 1885, New Orleans, La.; Time of holding meeting, last Tuesday in April.

COMMITTEE OF ARRANGEMENTS.

Samuel D. Logan, Chairman; S. E. Chaillè, E. S. Lewis, Joseph T. Scott, W. G. Austin, W. H. Watkins, J. P. Davidson, J. A. G. Fisher, Geo. W. Lewis, B. A. Pope, W. C. Wilson, M. Schuppert, Geo. J. Friedrichs, F. Loeber, D. Jamison, G. K. Pratt, L. F. Salomon, J. H. Bemiss, Geo. Lawrason, C. U. Gaudet, Sam'l M. Bemiss, C. J. Bickham, Chas. Turpin, Jno. Carter, A. W. DeRoaldes, S. S. Herrick, W. S. Mitchell, E. T. Shepard, E. Souchon, T. D. Layton, T. S. Dabney, S. R. Olliphant, Edward Harrison, A. B. Miles, Joseph Holt, P. B. McCutchon, F. H. Parham, G. B. Underhill, Stanhope Jones, E. Chassaignac, J. Dell'Orto.

ASSISTANT SECRETARY.

W. H. Watkins, New Orleans, Louisiana.

BOARD OF TRUSTEES FOR JOURNALIZING THE TRANSACTIONS.

J. M. Toner, Washington, D. C., President;

E. M. Moore, Rochester, N. Y.;

Leartus Connor, Detroit, Mich.;

J. H. Packard, Philadelphia;

H. F. Campbell, Augusta, Ga.;

A. Garcelon, Lewiston, Me.;

P. O. Hooper, Little Rock, Ark.;

L. S. McMurtry, Danville, Ky.;

J. H. Hollister, Chicago, Ill., Secretary.

OFFICERS OF THE SECTIONS:

"Practice of Medicine."

Chairman—H. Didama, Syracuse, N. Y.;

Secretary—G. M. Garland, Boston, Mass.

"Obstetrics and Diseases of Women."

Chairman—R. S. Sutton, Pittsburgh, Pa.;

Secretary—J. T. Jelks, Hot Springs, Ark.

ORIGINAL ARTICLES.

THE TREATMENT OF DIABETES MELLITUS.

BY AUSTIN FLINT, JR., M.D., PROFESSOR OF PHYSIOLOGY IN THE BELLEVUE HOSPITAL MEDICAL COLLEGE.

Read in the Section on Practice of Medicine and Materia Medica, of Am. Med. Association, May, 1884.

MR. CHAIRMAN AND GENTLEMEN:—It would not be possible, within the limits to which this paper is necessarily restricted, to discuss satisfactorily the pathology or even the clinical history of diabetes mellitus, although the disease in question is one of the most interesting, as well as obscure affections which the physician is called upon to treat. While the study of diabetes and its attendant disorders of general nutrition presents difficulties, as regards questions of causation and pathology, that seem almost insurmountable, when attention is once directed to the simple problem of the presence of sugar in the urine, this condition is now easily and certainly recognizable. It is probably true that sugar exists in the urine of a certain number of persons, unattended with symptoms, so that it is detected only by accident or may never be revealed, such persons having no apparent occasion to seek medical advice. In an experience in life insurance examinations extending through a period of nearly thirteen years, I have found a small quantity of sugar in the urine of applicants who supposed themselves to be perfectly healthy; but within the time mentioned, only five such cases have come under my observation. Three of these applicants are now living and are presumably in good health, the sugar in the urine having been noted from eight to twelve years ago; one case was lost sight of, and one applicant is reported to have died of hæmoptysis nine months after the examination of the urine. During the time mentioned; viz., twelve years and nine months, I examined 1884 persons who supposed themselves to be in good health, and nearly always made examinations of the urine. All of the applicants, with one or two exceptions, were males. The proportion, therefore, of apparently healthy persons in whose urine I have found sugar is very small (1 in 377); but even this shows that sugar may be present in the urine, either as a transient or an insignificant condition or existing without any of the general symptoms of diabetes.

In the great proportion of cases of diabetes that come under observation, attention is directed to the condition of the urine by certain general symptoms; such as excessive thirst, persistent polyuria, a sensation of dryness of the mouth and fauces, fatigue after moderate muscular exertion, or some slight affection of the external genitals. In a case of diabetes that I have had under treatment for nearly four years, now under observation, the patient first consulted a physician for herpes progenitalis, which led to an examination of the urine. In females, persistent pruritus of the vulva is often the first circumstance pointing to the possible existence of diabetes. In several cases, I have detected sugar in the urine when pruritus vulvæ was the only trouble complained of by patients. So constant is this symptom, that diabetes should always be suspected when the pruritus persists without any apparent cause and resists ordinary measures of treatment. The pruritus is seldom absent when the proportion of sugar in the urine is considerable.

Detection of Sugar in the Urine.—As far as purely clinical examination of the urine is concerned, the great desideratum is a simple test, easy and rapid in its application, upon which one can rely with absolute confidence. I shall pass over, without discussion or even mention, the different tests employed for the detection of sugar, except the one known as Fehling's. When the Fehling's liquid is properly prepared and carefully used, there can be no error in the results. If a quantity of this test, however, be made and kept for some time, it is liable to change so as to become more or less unreliable. This want of stability in the test-liquid has long been recognized by those accustomed to urinary examinations; and a few years ago I prepared three separate liquids, which I mixed in certain proportions for use as required. Even this did not prove to be entirely satisfactory. Within the last year, two separate liquids have been prepared by Dr. E. R. Squibb, and are kept by him for sale, in which form, the test seems to leave nothing to be desired in the qualities of accuracy and ease of application. The test, as it is now prepared by Dr. Squibb, is simply perfect; but so much depends upon its proper use, that I shall venture to detain the "Section" with an account of its application and the necessary precautions to be adopted. These precautions are simple and demand no special skill; but they often become very important, especially in determining with certainty the absence of sugar.

The two test-liquids are prepared by Dr. Squibb according to the following formulæ:

For the Solution of Cupric Sulphate.—Use purified sulphate of copper, in granular crystals, air-dried. Weigh 277 grains (17.32 grammes) of the salt and dissolve it in about 4 fluidounces (120 c.c.) of distilled water, adding about 4 minims ($\frac{1}{4}$ c.c.) of pure sulphuric acid. Add distilled water to this solution to make $8\frac{1}{2}$ fluidounces. (260 c.c.)

For the Solution of Alkaline Tartrates.—Weigh 2 ounces, 391 grains (87.5 grammes) of re-crystallized sodio-potassic tartrate, or Rochelle salt, and dissolve it in about 6 fluidounces (175 c.c.) of distilled water. Filter the solution, if necessary, and add to it a clear solution of 386 grains (25 grammes) of caustic soda in about $1\frac{3}{4}$ fluidounces (50 c.c.) of distilled water. Add distilled water to this solution to make $8\frac{1}{2}$ fluidounces (260 c.c.)

These two solutions are to be kept in separate bottles for use. If they be made with accuracy and mixed together in equal proportions, 200 grains of the mixture will be decolorized by exactly one grain of sugar, or each cubic centimetre of the mixture will be decolorized by 0.005 of a gramme of sugar. The liquids can therefore be employed for quantitative estimates, although I shall describe the use of the test simply for determining the fact of the presence or absence of sugar.

For use in qualitative analysis, the two liquids may be roughly mixed in about equal proportions in a test-tube, or they may be measured accurately and diluted with about an equal volume of distilled water. The latter process should be resorted to in all delicate analyses.

For ordinary use the following process may be employed:

Mix in a test-tube equal volumes of the two liquids so that the mixture will extend in the tube to the length of about an inch.

Bring the mixture to the boiling point and then add to the boiling test a quantity of urine equal to that of the test.

Bring the mixture of the test-liquid and urine to the boiling point and then allow it to cool.

If no distinct and opaque reddish or yellowish precipitate be present when the mixture of test and urine has become cool after the second boiling, it is absolutely certain that no sugar is present.

All these precautions are essential; and I have repeatedly examined specimens of urine in which the characteristic precipitate due to the presence of sugar did not occur until one or two minutes had elapsed after the second boiling.

In very delicate testing, take a definite quantity of the copper-solution, add an equal quantity of distilled water, add then of the solution of alkaline tartrates a quantity equal to the quantity of the copper-solution, and add finally distilled water in the same quantity. When this mixture is boiled, if the test be not absolutely perfect, there will be a precipitate before the urine is added. The mixture, if perfect, may be used in the same way as the simple undiluted mixture of the two solutions.

When sugar is present in the urine, an opaque yellowish or reddish precipitate appears at some time during the process, the promptness of its appearance

and its quantity being in direct proportion to the quantity of sugar.

It is often important to be able to determine, at least approximatively, the quantity of sugar discharged in twenty-four hours or its proportion per fluidounce. Using the volumetric process, this estimate requires some practice and occupies from twenty to thirty minutes; but the "differential density method" recommended by Roberts, is very simple and is sufficiently accurate for ordinary purposes. With a little practice, indeed, it may be employed by intelligent patients.

Two specimens of diabetic urine are taken, about four ounces of each, one for comparison and the other for analysis. To one is added a lump of German yeast, about the size of a filbert, in a bottle with a cork nicked to allow the escape of gas; and the other specimen is placed in a similar bottle tightly corked. The bottles are then put aside in a warm place, as the mantel-piece in winter or in the sun in summer. In the course of twenty-four hours, fermentation will have been completed in the specimen to which yeast has been added. If the specific gravity of the two specimens be then compared, the fermented specimen will be found much the lighter, from loss of the sugar which has been decomposed into alcohol and carbonic acid. The difference in the density of the two specimens, expressed in degrees of the urinometer, will represent the number of grains of sugar per fluidounce in the urine. For example, if the specific gravity of the fermented specimen be 1010, and the specific gravity of the unfermented specimen, 1040, the urine contains thirty grains of sugar per fluidounce. In this process, it is essential to compare the density of the two specimens at the same temperature. If German yeast cannot be obtained readily, about a teaspoonful of ordinary baker's or brewer's yeast may be used.

Relations of the Specific Gravity of Urine to the Proportion of Sugar.—It has long been recognized that the specific gravity of the urine bears no definite and constant relation to the proportion of sugar in cases of diabetes. In a case that came under my observation in December, 1883 and has been under treatment until the time of writing (April, 1884) on Dec. 29, 1883, the specific gravity was 1038, with 28.4 grains of sugar per fluidounce. The next day, the specific gravity was 1036 and the proportion of sugar was nine grains per fluidounce. In another very interesting case now under treatment, I found four grains of sugar per fluidounce, the urine having a specific gravity of only 1011½. These remarkable variations in the specific gravity, occurring without any relation to the quantity of sugar, are generally dependent upon the proportion of urea, the absolute quantity of which is often very largely increased in cases of diabetes. I have often found crystals of uric acid as a persistent condition in diabetic urine, sometimes associated with a deposit of oxalate of lime.

The time allotted to me does not admit of a discussion of the possible relations of the nutritive conditions connected with diabetes to the excessive elimination of urea or the frequent presence of crystals of uric acid; but it is very important to remem-

ber that urine of a comparatively low specific gravity may contain sugar. Within a week, in another case in which the urine is examined every three or four days, I found a marked sugar-reaction in a specimen of urine with a specific gravity of 1010. I have also repeatedly found sugar in urine of a specific gravity of about 1020, the quantity of urine in twenty-four hours being normal. The fact, then, that the quantity and specific gravity of the urine are normal does not in itself exclude sugar; although, in most cases of diabetes, the quantity of urine is increased and its specific gravity is notably high. In a case of diabetes very elaborately reported by Pavy, sugar was found in the urine when the specific gravity of the specimens was, on different occasions, 1010, 1011, 1012, and 1013.¹ In cases in which diabetes is suspected, the physician is not justified in excluding the disease when he finds no increase in the quantity of urine and a normal specific gravity; and the facts just mentioned show that, in all cases of this kind, the urine should be carefully tested for sugar.

What constitutes Diabetes Mellitus?—A patient with abnormal thirst, dryness of the mouth, suffering from fatigue following slight muscular exertion, progressively losing strength and weight, and passing an abnormally large quantity of urine of high specific gravity and containing sugar, has the disease known as diabetes mellitus; but the various symptoms just enumerated may exist in greater or less degree or some of them may be absent. In addition to these symptoms, others may exist; such as, abnormal dryness of the skin, deficient perspiration on exercise or in warm weather, pruritus of the vulva, a tendency to furuncles, unusual liability to "take cold," reduction in the general temperature of the body, an excessive appetite, failure of the generative functions, etc., but these are not necessarily present in cases of diabetes.

On the other hand, none of the general symptoms that I have mentioned may be observed; the urine may be normal as regards quantity and specific gravity; but still sugar may constantly exist in small quantity. In such instances, which are not very infrequently observed, the constant, necessary, and invariable symptom of diabetes is present; namely, glycosuria. Strictly speaking, perhaps, patients with no general symptoms, with no increase in the quantity of urine, and with urine of normal specific gravity, may be said to be affected with glycosuria, but not to have diabetes. In the great majority of cases, however, unless the glycosuria be transient and dependent upon some recognizable or temporary cause, certain of the general symptoms of diabetes will sooner or later become developed, unless the glycosuria be removed by treatment. Still, even without treatment, persons may live in what seems to be perfect health for years, constantly passing considerable quantities of sugar. I can now call to mind three cases of this kind; and several cases, in which I have found sugar in the urine without any other diabetic symptoms, have passed from under my observation.

I shall have little to say concerning the etiology and pathology of diabetes. The brilliant physiolog-

ical experiments, which began with the discovery of the sugar-producing function of the liver by Claude Bernard, in 1848, have failed, in a great measure, to fulfil the expectation that they would lead to a definite comprehension of the pathology of diabetes. I believe it to be true that the liver is a sugar-producing organ. The experiments of Pavy, in which he showed that the liver-substance does not actually contain sugar during life were, in my opinion, harmonized with those of Bernard, by experiments made by me in 1869.¹ In these experiments, I found no sugar in an extract of the liver taken from a living dog and put into boiling water in ten seconds, while sugar was present in blood taken from the hepatic veins. I am convinced that the liver is constantly forming sugar during life, but that this sugar, as fast as it is produced, is washed out of the sugar-producing organ by the blood-current. Experiments have shown, also, that the sugar contained in the food, as well as that resulting from the digestion of starch, is normally destroyed in the organism. That the sugar-forming function of the liver may become exaggerated beyond the power of the organism to destroy the excess thus produced was demonstrated by the remarkable experiments of Bernard, in which he induced temporary diabetes in animals by mechanical irritation of the floor of the fourth ventricle, by stimulating the pneumogastric nerves, or by introducing irritating vapors into the lungs; but, although cases of traumatic diabetes occur in the human subject, they are exceedingly rare. No such case has as yet come under my observation.

I do not propose, at this time at least, to offer any theory with regard to the causation or pathology of diabetes, the cause of death in the so-called diabetic coma, or the supposed development in certain cases of acetonæmia. The discussion of these points has, up to the present time, been very unsatisfactory. We all know that patients presenting, in a well-marked degree, certain characteristic symptoms, in addition to glycosuria, are affected with a very grave disease, the pathology of which is imperfectly understood. The sugar resulting from digestion is in great part discharged in the urine. The nutritive processes are seriously disturbed. The power of resistance to other diseases is impaired. What is remarkable and quite interesting, in its relations to our ideas of the production of animal heat, the failure to consume the hydrocarbons seriously affects the power of resistance to cold, and the general temperature of the body is habitually 95° or 96° Fahr., instead of about 98½°. This latter point I state upon the authority of many writers; and in a case now under treatment, the temperature in the axilla has constantly been about 96½°. As the patient improved, the temperature was increased to a fraction over 97°, but it has not yet reached the normal standard.

Being brought, then, face to face with a disease, very obscure in its pathology, and not infrequent in its occurrence, the practical question, to which I intended to devote the main part of this paper, is, how

¹PAVY, *Nature and Treatment of Diabetes*, London, 1869, p. 268, et seq.

¹FLINT, JR. *Experiments undertaken for the Purpose of reconciling some of the Discordant Observations upon the Glycogenic Function of the Liver*.—*New York Medical Journal*, 1869, vol. viii, p. 373, et seq.

far it is amenable to treatment. To this question I shall devote what remains of the time at my disposal.

Treatment.—In a course of lectures by Cantani, delivered at the clinical hospital of the University of Naples, in the spring of 1872, there occurs the following statement, italicised by the author:

"Diabetes has become to-day a disease easily and certainly curable, provided that the treatment (cure) be not begun too late."

The cases which Cantani details in support of this rather startling statement show certainly the most remarkable effects of treatment. Judging from the account of these cases, the general proposition that diabetes is a disease, in the main easily and certainly curable, is not too decided and absolute. Since I have been engaged in treating cases of this disease, my experience, though not extending over many years, has led me to the conviction that the claim made by Cantani is not extravagant.

In the great majority of cases in which patients will submit to certain measures of treatment as soon as it is established that they are suffering from diabetes, or as soon as glycosuria is recognized, it is possible to effect either a cure of the disease or a removal of most of the characteristic symptoms, with the exception, perhaps, of the occasional appearance of a small quantity of sugar in the urine.

Time does not permit me to discuss fully the treatment recommended by different writers. Cantani relies mainly upon dietetic measures, although he attaches considerable importance to the exhibition of lactic acid and the alkaline lactates. Of course the treatment by eliminating sugar and starch from the diet is by no means novel. Dating from the time of Rollo, it has had the earnest support of Bouchardat, Pavy, Seegen, and many others. I desire to state at the outset, that the main and almost the sole reliance of the physician should be upon diet; and that the suppression of starch and sugar should be practically absolute. Bearing this fact constantly in mind, in considering the different measures of treatment, I shall divide them into dietetic, general, and medicinal.

Dietetic Treatment.—In 1869, a patient was sent to me from Omaha, Neb., whom I found to be suffering from many of the distressing symptoms of diabetes.

On Nov. 20, 1869, he passed 224 fluidounces of urine in the 24 hours, with a specific gravity of 1.035. The quantity of sugar passed in the 24 hours was 18 ounces and 30 grains, and the quantity of urea was 624 grains. I recommended a diet-table by no means as rigid as the one I now employ, and he left for home. For several years I heard from this patient, either personally or through his physician in Omaha, from time to time, and he was reported as apparently well, but occasionally passing a small quantity of sugar. He continued the diet more or less faithfully for two or three years, but took a little bread. About five years after, I was accosted in the street by this patient, who reported himself as feeling perfectly well and giving but little attention to his diet. At this time I did not have an opportunity

of examining the urine. The patient has since died, and I heard from his widow that this occurred in August, 1881, his death being immediately due to inflammation of the bowels after a few days' illness. "The diabetes was much improved and troubled him very little."

This case, during the time when I was constantly receiving favorable reports, seemed to me to be quite remarkable; and in 1880, having frequent occasion to recommend a diet for diabetics, I carefully compiled an anti-diabetic diet-table, which I have since used constantly in cases that have come under my observation, and which I shall present as an appendix to this paper. In preparing this table, my object has been to secure a diet sufficiently nutritious but free from starch and sugar, using as a basis the admirable list given by Bouchardat;¹ and I have endeavored to adapt the articles and their preparation to the customs of our own country, adding to it, when possible, in order to secure the greatest available variety of food. Selecting, however, every dish known in the culinary art, without reference to the trouble or expense of its preparation, a rigid diet is by no means easy of enforcement. Patients at first have an intense craving for bread; and this desire is so nearly universal that almost all writers on diabetes suggest some substitute for this important article of food. I do not hesitate to say, however, without specifying any one of the so-called anti-diabetic breads and flours as especially bad, that all the articles of this kind in our markets are absolutely unreliable and most of them fraudulent. I have analyzed, or caused to be analyzed, nearly all of the so-called bran-flours, and gluten-flours, and have invariably found large quantities of starch. Two specimens said to be free from starch, which were analyzed with great care by a competent chemist, were found to contain a greater proportion of this principle than exists in ordinary wheat-flour. Most of the so-called diabetic breads are pasty, heavy, and become extremely distasteful. A patient now under occasional observation, having procured a new bread which was so agreeable to the taste that he took it freely and with relish, imagined that he had found at last an article which would be regarded by diabetics as the greatest boon. This bread was made of flour which contained about 80 per cent. of starch.² The effects of this fraud upon the patient were quite serious. His health had become nearly restored and the sugar had disappeared from the urine. Under the use of the bread, the sugar returned, and it was several weeks before it disappeared again under a strict diet. In the rigid dietetic treatment, bread should be absolutely interdicted, or, in case patients should refuse to submit to a strict diet, a small quantity of crust of bread taken with an abundance of butter may be allowed under protest.³

A rigid diet, without bread, should be continued

¹ BOUCHARDAT, *De la glycosurie ou diabète sucré*, Paris, 1875, p. clxxxvi.

² Ordinary wheaten flour contains about 70 per cent. of starchy matters.

³ Since this article has been in print, I have seen a bread made by George V. Hecker & Co., 205 Cherry street, New York City, made of wheaten flour said to contain only 5 per cent. of starch. This bread is light and agreeable, but it requires great care in its preparation. A specimen of the bread was examined by Prof. G. A. Doremus, who found a little more than one per cent. of starch.

until the sugar has disappeared from the urine and all the diabetic symptoms have been removed. Although many diabetics rebel under this regimen, and the execution of this measure demands, on their part, much self-denial and fortitude, patients may be encouraged to persevere, by the statement that the craving for saccharine and starchy articles is likely to diminish and may almost disappear after a few weeks. I have now under observation and treatment several patients who have actually lost all desire for most of the interdicted articles of food.

In cases in which the treatment is followed by an apparent cure, sugar disappearing from the urine, a gradual return to the normal diet should be begun about two months after the glycosuria has ceased; but it is of the greatest importance, during this part of the treatment, to keep patients, if possible, under constant observation, examining the urine at least once in five or six days. When the sugar disappears, patients may regard themselves as permanently cured, and no general symptoms present themselves for some time after glycosuria has returned under a mixed diet. Several unfortunate examples of this have come under my observation.

General Treatment.—Measures of general treatment are to be directed mainly to promoting the proper action of the skin, which is often harsh and abnormally dry, and to general muscular exercise. Systematic rubbing, as practiced by massage, and Turkish or Russian baths once a week, if they be not contraindicated by some complicating conditions, are useful. A reasonable restriction in the taking of liquids is quite important in diminishing the quantity of urine. Under the dietetic treatment the excessive thirst is almost always relieved; but when this persists, it may often be temporarily met, as far as dryness of the mouth is concerned, by taking small pieces of ice from time to time instead of drinking water. I do not know that any reliance is to be placed upon the use of the various mineral waters that are said to exert a curative influence over the disease in question. Alcoholic stimulants are to be avoided. I have seen several cases of diabetes in which the disease seemed to be attributable to the abuse of alcohol, especially the habitual and excessive drinking of champagne. In certain cases, some kind of alcoholic beverage seems to be necessary to maintain the vital powers. For this purpose, a fairly good, sound claret has seemed to me to be the best form in which alcohol may be taken. Spirits should be interdicted or given very sparingly, and not more than a pint of claret should be taken daily.

Patients suffering from diabetes lose, to a certain extent, their capacity for sustained mental effort. They should be cautioned, therefore, against excessive intellectual work. Mental anxiety and "worry" over business or other affairs exert a very unfavorable influence on the progress of the disease. In some cases apparently cured, I have noted a return of the glycosuria, which seemed to be fairly attributable to mental causes. The insomnia rarely demands the use of narcotics and is usually relieved with the other symptoms by the anti-diabetic diet.

The various minor complications that are liable to

occur can usually be overcome by appropriate treatment. The occurrence of boils is very common and they are likely to be persistent and annoying. When the tendency to boils is very marked, the sulphide of calcium is useful, although this agent does not seem to exert a curative influence over the diabetes itself. The sulphide of calcium has been recommended very highly as a remedy controlling the glycosuria; but it is often disagreeable to patients and disturbs digestion. In a few instances in which I have employed it for a considerable period, it has not seemed to affect the discharge of sugar, and I regard it as useful only to combat the furuncular tendency. It is dangerous to rely upon drugs to any extent in the treatment of this disease. Patients willingly put faith in remedies rather than in a rigid diet; but, after all, diet is the main and almost the only reliance in treatment.

A very important, and perhaps the most important, measure of general treatment is systematic muscular exercise, not carried to the extent of producing excessive fatigue. This may be taken in the form of gymnastics, or of out-door exercise, such as riding or athletic sports; but patients should always be cautioned to avoid "taking cold." If a patient suffering from diabetes can be made to develop his muscular strength by moderate and systematic exercise, not too prolonged, and followed by a proper and not excessive sense of fatigue and some perspiration, with a good reaction after bathing and rubbing, much will be gained in the way of treatment. This is strongly recommended by all writers upon diabetes.

The diminished power of resistance to cold which exists nearly always in diabetics renders it necessary to enjoin great care in avoiding exposure to the vicissitudes of the weather, and the constant protection of the body by warm clothing, especially flannels next the skin.

Medicinal Treatment. There is no remedy that exerts a curative influence over diabetes in the absence of proper dietetic measures. Opium, the bromides, sulphide of calcium, various mineral waters, and other medicinal agents that have been recommended from time to time, have all proved very unsatisfactory in practice. Of course it is difficult to estimate the value of drugs in this as in many other diseases, particularly as the physician is not justified, in my opinion, in neglecting to enforce a rigid diet which, in itself, in the great majority of cases, exerts a most decided influence over the glycosuria and the general symptoms. On theoretical grounds, Cantani recommends lactic acid, taken in the form of a "lemonade," in small quantities throughout the day. The formula for this mixture is the following:

Pure lactic acid..... 5iiss to 5v.

Aromatic water..... 5v to 5j.

Water..... Ojj.

This remedy is regarded by Cantani as useful in many cases but not essential. I have little experience in its employment.

Keeping in mind the small reliance to be placed in the efficacy of drugs unjoined with dietetic measures, I must bear testimony to the apparent advantage to be derived from the use of the arsenite of

bromine, recently proposed by Clemens. While I have not felt justified in using this remedy to the exclusion of the anti-diabetic diet in treatment, for the reason that the bad effects of an unrestricted diet frequently persist for some time, I have noted very marked effects from Clemens's solution in controlling the discharge of sugar and some of the distressing symptoms, particularly the excessive thirst; so that, aside from simple measures to relieve sleeplessness, constipation, or other intercurrent difficulties, I have lately been in the habit of prescribing, in addition to the diet, three drops of Clemens's solution, three times daily, in a wine-glass of water, after each meal, gradually increasing the dose to five drops. The following is the formula for this remedy, which I have had prepared by Mr. William Neergaard, 1183 Broadway, New York City, and which may be written for under the name of "Clemens's Solution of Arsenite of Bromine."

"Liquor brom-arsen consists simply of a chemical union of arsenious acid and bromine, dissolved in water and glycerine, in such a manner that two drops represent the twenty-fourth part of a grain of arsenite of bromine."¹

In a case of diabetes of more than five years' standing, now under treatment, the patient has been taking Clemens's solution constantly, with the exception of a single week, from Dec. 27, 1882, to April 2, 1884, more than fifteen months, without any unpleasant effects. I began with a dose of two drops, three times daily, gradually increased to five drops. On May 13, 1883, the urine having been free from sugar, with the exception of a trace on two or three occasions, for thirteen weeks, I stopped the arsenite of bromine for one week, the anti-diabetic diet being continued. At the end of the week, sugar was found in large quantity in the urine. The use of the arsenite of bromine was then resumed. At the end of the first week, the sugar still existed in small quantity. At the end of the second week, the sugar had disappeared and there was no return of glycosuria for six weeks. The patient then left the city and committed many indiscretions in diet. Seven weeks later, I examined a specimen of urine and found it loaded with sugar, with a specific gravity of 1.030. While absent from New York, the patient had indulged in peas, egg-plant, stuffed tomatoes, green corn, ice-cream, charlotte russe, peaches, raspberries, blackberries, and melons. On September 20, after returning to New York and resuming a strict diet with the exception of the crust of half a white roll three times daily, the patient improved. The urine, on September 20 had a specific gravity of 1.031 and was loaded with sugar. The following week the sugar was much diminished in quantity, and it disappeared at the end of the second week.

Summary of Treatment.—The more I study the cases of diabetes that have come under my observation, especially those that are now under treatment, in connection with the writings of those who have faithfully followed the dietetic plan, notably Bouchardat and Cantani, the more thoroughly am I convinced that the prognosis in a recent and uncomplicated case of this disease in an adult is invariably

favorable, provided, always, that the proper measures of treatment be rigidly enforced. In the hope of convincing the profession that this statement is reliable, I shall, at the risk of what may appear to be needless repetition, give a summary of treatment, with brief statements of the progress of cases that I am now actually observing.

At the outset, patients should be impressed with the fact that they are suffering from a grave disorder, and that everything depends upon their full coöperation in the treatment, which treatment is essentially dietetic. The diet-table should be carefully studied, and the diet regulated and carried out absolutely.

In case a rigid anti-diabetic diet does not promptly influence the glycosuria, it may be well to subject a patient to an absolute fast for twenty-four hours and follow this with the anti-diabetic regimen. This rather harsh measure is suggested by Cantani. I shall not hesitate to employ it in cases in which it may seem to be required, although no such case has as yet come under my observation.

The various measures that I have mentioned under the head of *General Treatment* should be enforced, especially systematic daily muscular exercise. A moderate system of training on the plan adopted by athletes is most useful; and this, if continued, will do much to render a cure permanent after a return to the normal diet.

The return to a normal diet should be gradual, and during this time the urine should be frequently examined, the rigid diet being resumed at the first reappearance of sugar in the urine; but all alcoholic excesses, the immoderate use of sweet fruits, and any use of sugar, should be interdicted at all times. A patient who has once had diabetes is always liable to a return of the disorder. He must lead a thoroughly careful, hygienic, and temperate life. In the words of Bouchardat, "you will not be cured except on the condition that you never believe yourself to be cured."¹

While I believe that the physician is justified in encouraging patients to expect relief, and even cure, in recent, uncomplicated cases, the diet is all important, and its regulation cannot be expected to be perfect without professional aid in its enforcement. A diabetic is never safe from a return of his disease, even when he believes himself to be cured; and under no circumstances should he pass more than a few weeks without an examination of the urine.

The arsenite of bromine, or Clemens's solution, appears to be useful. We may begin with 3 drops three times daily in a little water immediately after eating, gradually increasing the dose to 5 drops. This may be continued for weeks and months without producing any unfavorable effects; but the administration of this remedy does not supply the place of the dietetic treatment, which should be enforced in all cases. A rigid diet should be continued for two months, at least, even in the mildest cases of the disease. It may be necessary, in certain cases, to continue it for a longer period, even twelve or more months.

There is probably no such disease as intermittent

¹ *Medical Times*, Philadelphia, Dec. 2, 1882, p. 160.

¹ BOUCHARDAT, *De la Glycosurie ou Diabète Sucré*. Paris, 1875, p. 49.

diabetes. In some instances glycosuria occurs during the season of sweet fruits, when they are indulged in excessively, and disappears when the diet is changed; but these are mild cases of diabetes, excluding those in which a transient glycosuria follows the inhalation of irritating vapors, the taking of anæsthetics, etc.

Robust or corpulent persons are more tolerant of the disease than those who are feeble or spare, and the glycosuria yields, in such cases, more readily to treatment.

Diabetes occurs at all ages. Bouchardat mentions a case in an infant of 3 years, although the disease is rare before the age of 12. The most unfavorable cases are those which occur before the age of puberty. An adult male presents the most favorable conditions for cure. In old persons, when the disease is of long standing, the dietetic treatment will secure practical immunity from nearly all the distressing symptoms, although the glycosuria may not be entirely removed.

A study of any of the diet-papers recommended will make it evident that those who are able to follow the required regimen, without regard to the cost of articles of food, present much more favorable conditions, as regards the prospect of cure, than persons in straightened or indigent circumstances. Diabetes, however, occurs in all classes and is by no means a rare disease. A hospital devoted to such cases, where the dietetic treatment could be strictly carried out, would be a boon to the rich and poor alike.

Cases.—I have accounts, more or less complete, of fifty cases of diabetes. A certain number of these cases have been lost sight of; others were followed out in their histories to a fatal termination; and twelve, exclusive of a few that are reported to be cured, are still under either observation or treatment.

Of these fifty cases, sixteen have been lost sight of, nineteen are either known to be living or are under observation, and twelve have died at periods between nine months and over twelve years after I first examined the urine.

Of the seven patients who are living, but whom I do not consider as under observation, one passes sugar constantly and is under an imperfect anti-diabetic diet, but is in what may be called fair health; two are reported as cured, although I have not examined the urine for a long time; four I simply know to be living.

The twelve cases that are under observation are instructive as indicating the value and influence of treatment.

Case A.—The patient, a gentleman thirty-eight years of age, first became aware that he suffered from diabetes mellitus about June 1, 1883. He is five feet five inches in height, and weighs one hundred and twenty-nine pounds. A year ago he weighed one hundred and sixty pounds. He suffered from excessive discharge of urine, with increased appetite, thirst, dryness of the mouth, sleeplessness, fatigue on slight exercise, and, indeed, most of the symptoms of diabetes; but a careful physical examination failed to reveal any other disease. At the time I first saw him, he had been taking quinine and various tonic remedies and had been subjected to an imperfect anti-

diabetic diet. At this time, December 29, 1883, he passed eighty ounces of urine in twenty-four hours, containing in all 3,072 grains of sugar. He was immediately put upon a strict diet, taking no bread, drinking very little, and relieving the thirst temporarily by taking pieces of ice. In addition, he took three drops of Clemens's solution three times daily, and continued to take ten grains of quinine each day. After forty-eight hours of this treatment, his intense thirst and excessive urination disappeared, but he expressed himself as feeling rather weak although generally much better. The effect, however, upon the discharge of sugar was remarkable. He passed, during the second twenty-four hours of treatment, forty-three ounces of urine, and the total quantity of sugar was reduced from 3,072 grains to 387 grains.

I heard from this patient January 19, 1884, and received a specimen of the urine of the twenty-four hours of January 17th. For the twenty days since December 29, 1883, he had maintained an absolute anti-diabetic diet, taking no bread. During this time, he took three drops of Clemens's solution three times daily. He had gained three-quarters of a pound in weight. He had suffered somewhat from indigestion but was otherwise quite well. "The very large appetite and thirst are very materially lessened." The quantity of urine in twenty-four hours was forty-eight and one-half fluid-ounces; specific gravity, 1.026; absolutely no sugar; there was rather an abundant deposit of amorphous urates with a number of crystals of uric acid. As far as the diabetic condition is concerned, the general symptoms had disappeared as well as the sugar in the urine.

On January 25, 1884, the dose of Clemens's solution was increased to five drops three times daily. The urine was free from sugar. There was no sugar in the urine on January 27 and 29. He was then allowed the crust of half a French roll at breakfast.

On February 4, 1884, I saw the patient again. He had been at home and had committed some slight indiscretions in diet. The urine had a specific gravity of 1.030 and contained a small quantity of sugar. The strict diet was resumed.

On February 10, 1884, there was a trace of sugar in the urine.

On February 24, 1884, the patient still under a strict diet and the use of Clemens's solution, there was no sugar in the urine. The patient went home, feeling perfectly well, and promised to send a specimen of urine in two weeks. At no time since the beginning of treatment was there any excessive quantity of urine.¹

Case B.—The patient is a gentleman fifty-seven years of age, five feet eleven and one-half inches in height, weighing one hundred and twenty-two pounds. He had suffered from diabetes to his knowledge for about one year, with thirst, fatigue after moderate exertion, and other mild symptoms. He had been under a moderate anti-diabetic diet for some weeks. After he came under my observation, his urine, under a strict anti-diabetic diet, was either entirely free from

¹On April 29, 1884, I received a specimen of urine from this patient. The quantity in twenty-four hours was said to be about fifty fluidounces. The specific gravity was 1.022½ and it contained a trace of sugar. The general health was reported as perfect.

sugar or contained merely a trace, for ten months. He had no symptoms and regarded himself as cured. For about three months he took four drops of Clemens's solution three times daily.

On January 17, 1884, he presented himself, passing a large quantity of urine of a specific gravity of 1.027, and loaded with sugar. Having regarded himself as permanently cured, he had returned to his old diet, including sugar, and had stopped the arsenite of bromine for six months. He felt perfectly well but had noticed for some days that he was passing a large quantity of urine. He was again put upon an anti-diabetic diet (which I fear is not strictly followed) with six drops of Clemens's solution twice daily. On February 7, 1884, he passed a normal quantity of urine of a specific gravity of 1.022, containing but a trace of sugar.

In this case, I cannot secure a strict adherence to the diet and regular examinations of the urine.¹

Case C.—This patient has been under observation since October, 1880. He was at that time 53 years of age, five feet eight and one-half inches in height, and weighed from 168 to 172 pounds. The diabetes had been recognized a few weeks before he came under my observation, and he had been subjected to an imperfect anti-diabetic diet. He was immediately put upon a strict diet, and from October 21, 1880, to May 18, 1881, his urine generally contained no sugar, although there was occasionally a trace. In this case the diet was strictly followed, and the patient soon lost his desire for prohibited articles, even bread.

On May 18, 1881, he was allowed the fruits in season, to be taken without sugar. On June 27 he was allowed a little bread. His urine was practically free from sugar until February 17, 1882, with the exception of an occasion on November 5, 1882, when it had a specific gravity of 1.029 and contained considerable sugar following a slight excess at table in taking claret and whiskey and water.

On February 17, 1882, his urine had a specific gravity of 1.026 and contained considerable sugar. He had been living rather freely for some time without committing any actual excesses at table. He moderated his living and was given, in addition to the strict diet, one-quarter of a grain of sulphide of calcium three times daily. From February 17, 1882, to September 1, 1883, his urine was practically free from sugar when examined on ten different occasions, once, only, presenting a mere trace. During the entire treatment he has taken considerable exercise in walking. He took the sulphide of calcium rather irregularly for six months, but it was very disagreeable.

On January 11, 1883, he began to take the arsenite of bromine, which he continued rather irregularly.

On January 23, 1884, his weight had increased to 175½ pounds. Since September 1, 1883, his diet had been practically unrestricted. His urine had a specific gravity of 1.021 and contained a small quantity of sugar. He was put on a moderate anti-diabetic diet and the dose of arsenite of bromine was

increased to five drops. On February 7, 1884, the sugar was still marked in the urine, but he indulged rather too freely in claret at dinner and drank some brandy and soda during the evening. From February 7, to April 3, 1884, the urine had been nearly always free from sugar.

This may almost be called a case of cure. For the greatest part of the time from October, 1880, to April, 1884, three and one-half years, the urine has been practically free from sugar, for some of the time under an ordinary diet. During this period, sugar has appeared temporarily and in small quantity, possibly as a consequence of occasional indiscretions in the use of wine, which could not by any means be regarded as excesses in a person in ordinary health.¹

Case D.—This is the case of a lady, rather stout, fifty-nine years of age, who came to me for treatment in December, 1882. The patient has already been referred to in connection with the fact of the existence of sugar in urine of a low specific gravity, (1.011½) and the return of glycosuria immediately following the suspension for one week of the administration of arsenite of bromine.

In December, 1880, the patient was in a deplorable condition, suffering from some of the most distressing symptoms of diabetes. She suffered intensely from thirst, night and day, and was forced to pass the urine nearly every hour. She also suffered greatly from pruritus vulvæ. Her disease was of five years' standing, and she had been subjected to various forms of treatment, but never to a strict diet. She had consulted many distinguished physicians in this country and in Europe.

On December 16, 1882, she passed 128 ounces of urine, of a specific gravity of 1.036, containing twenty-two grains of sugar per fluidounce, or 2,816 grains in the twenty-four hours. The next day she was put upon a strict anti-diabetic diet.

On December 22, 1882, the daily quantity of urine was reduced to 52 ounces, with a specific gravity of 1.026, containing eight grains of sugar per fluidounce, or 416 grains in the twenty-four hours. The urine constantly presented crystals of uric acid. The thirst, pruritus, and constant desire to pass urine were relieved.

With the exception of one week, this patient took Clemens's solution, two drops three times daily, the dose finally increased to five drops, from December 27, 1882, to April 2, 1884. The treatment during this period consisted of the diet and Clemens's solution, with occasional remedies to act upon the bowels. She has been almost constantly under treatment, and I made 91 examinations of the urine up to April 6, 1884. Her urine is now examined regularly once a week.

Under treatment, the quantity of sugar in the urine diminished until the glycosuria disappeared January 27, 1883, about thirty days after the first examination. From January 27, 1883, to April 6, 1884, with the exception of about six weeks passed at a watering-place in the summer of 1883, under very unfavorable

¹I saw this patient on April 29, 1884, and he reported himself as perfectly well, but I did not have an opportunity of examining the urine.

¹On April 28, 1884, this patient reported himself as perfectly well. His urine had a specific gravity of 1.020½ and contained no sugar. The diet had been not absolutely strict but was what may be called moderately anti-diabetic.

conditions as regards diet, the urine has either been free from sugar or has contained a very small quantity. The quantity of urine has been constantly normal, and the general diabetic symptoms have never reappeared. She now uses the anti-diabetic diet with the crust of one-half of a French roll at each meal, a pint of cream daily, and a little fruit in season.

While this cannot be called an instance of perfect cure, the fact that the patient lives comfortably and in apparently good health under a diet that is not particularly irksome shows that cases of long standing and presenting very unfavorable features are by no means hopeless. This case presented to a remarkable degree the example of a loss of desire for prohibited articles of food. She now looks forward to eating melons in season, which is about the only strong wish she has expressed for food not suited to her condition.¹

Case E.—The patient in this case is a gentleman about fifty years of age, living in Ohio. I examined his urine May 24, 1878, and November 17, 1881, for some reason not connected with a suspicion of diabetes and found no sugar. On May 4, 1882, I again examined the urine, on account of certain diabetic symptoms, and found a large quantity of sugar. He was at once put on the anti-diabetic diet, which he attempted to carry out by himself at his home in Ohio. In January, 1884, he reported that all his symptoms had been relieved and that he suffers nothing unless he commits indiscretions in diet.

Case F.—The patient in this case is a gentleman about fifty years of age, and of medium muscular and adipose development. Having been suffering for some months from diabetic symptoms, his urine was examined by me on March 22, 1878. I then found a specific gravity of 1022 and a large quantity of sugar. He was at once put upon a moderate anti-diabetic diet.

On April 26, 1878, I found the urine normal, and the diabetic symptoms had disappeared. Between April 26, 1878, and January 10, 1882, I examined the urine seven times, always finding it normal.

On October 14, 1882, he passed ninety-six ounces of urine in the twenty-four hours, with a specific gravity of 1027 and containing 4 grains of sugar per fluidounce. His diet for some time had been irregular, and he had depended on various remedies, such as the bromides and the sulphide of calcium. He then began to take the arsenite of bromine, but his diet, though moderately anti-diabetic, was still imperfectly regulated. His urine, examined February 20, May 18, and May 28, 1883, contained a small quantity of sugar. On August 15, 1883, I examined the urine and found a trace of sugar.

This patient suffers very little from diabetic symptoms. I have little doubt that the glycosuria could be arrested by a few weeks of strict dietetic treatment.

Case G.—The patient is a lady, rather stout, and

about seventy-five years of age. Attention was directed to the urine on February 7, 1884, by excessive thirst and urination, with pruritus vulvæ. Before I examined the urine, it was reported to me that she was passing it in large quantity, the specific gravity being 1040, and that it was loaded with sugar. Under an anti-diabetic diet and the arsenite of bromine, in three days the quantity of urine was reduced to the normal standard and the diabetic symptoms disappeared. I examined the urine on February 13, 19, 28, March 4, 11, 17, 21, 25, 31, and April 5, 1884. The urine, with one exception, presented sugar in small but variable proportions, but its quantity was usually normal, and the specific gravity varied between 1007 and 1020. The urine on one occasion, with a specific gravity of 1010, contained a trace of sugar. On March 17, the urine had a specific gravity of 1007 and contained no sugar. The general diabetic symptoms are now entirely relieved. The only fault in the diet is that the patient takes a quart of milk daily. The progress of this case is quite favorable up to the present time.²

Case H.—The patient is a large and rather corpulent man, about 60 years of age. I examined the urine December 27, 1882, and found it with a specific gravity of 1027 and containing a considerable quantity of sugar. He was at once put upon the anti-diabetic diet. Under this treatment the glycosuria and other diabetic symptoms disappeared. In July, 1883, he was attacked with hemiplegia, from which he has substantially recovered. He was reported in March, 1884, as perfectly well, having returned to the normal diet.

Cases I, J, K and L.—These are cases of patients who are constantly passing sugar in large quantities, under little or no treatment, but who enjoy fair health. In one of these cases the patient obstinately refuses to regulate the diet, and although he suffers but little from diabetic symptoms, he has become greatly reduced in weight and strength within the past two years. A young daughter of this patient, whom I saw repeatedly and who never followed out the anti-diabetic diet, died of diabetes about three years ago. Another patient has fair health under a rather irregular diet. He is so situated as to be unable to carry out a strict regimen. The two other patients are large and corpulent men, who pass immense quantities of sugar, with no restriction in diet or in drinking.

Of the fifteen cases of death the reports are generally imperfect. Four are reported as having died of diabetes; one, of diabetic coma, possibly acetonaemia; three, of albuminuria; one, of apoplexy; one, of hæmoptysis; one, of "inflammation of the bowels"; and in the remaining four cases I have not been able to learn the cause of death.

Case M.—I have already referred to this case. The patient was a stout, heavy man, about 40 years of age. I examined him November 20, 1869. He then passed 224 ounces of urine in the twenty-four hours,

¹ The urine of this patient is examined regularly once a week, and there has been no sugar, with the exception of a trace on one occasion, for twelve weeks. The last examination was made on May 4, 1884, and no sugar was found. With the exception of sugar, the diet has been but little restricted for three weeks. For the last three weeks the patient has been taking about a pint daily of the lactic acid drink recommended by Cantani.

² From April 5 to May 2, 1884, I have made six examinations of the urine. The specific gravity has been between 1012½ and 1020 and a small quantity of sugar has always been noted, but there have been no general diabetic symptoms. The diet has not been rigidly carried out.

³ This patient died of apoplexy, June 1, 1884.

with a specific gravity of 1035, containing 18 ounces and 30 grains of sugar, and 624 grains of urea. He was immediately put upon a moderate anti-diabetic diet and returned to his home in Nebraska. I heard from time to time for several years that he enjoyed good health and had little or no glycosuria unless he committed serious indiscretions in diet. He died of "inflammation of the bowels," after a short illness, in August, 1881, nearly twelve years after I first saw him, in 1869.

Case IV.—On November 6, 1879, I saw in consultation a lady about 58 years of age, rather spare in figure, who had been suffering for some months with diabetes. At this time the quantity of urine was not notably increased, the specific gravity was 1030, and it contained a small quantity of sugar. The treatment had consisted mainly of an imperfect anti-diabetic diet. A more rigid diet was recommended, but it was not strictly enforced. On November 10 and 15, 1877, the urine contained a trace of sugar. On November 29, 1877, the urine was free from sugar, and the patient was much improved. She left for her home in Cuba, and I saw her again on Sept. 2, 1880, when the urine was still free from sugar. In July, 1881, she was passing large quantities of sugar, and I learned that for several months the diet had been unrestricted and she had eaten sweets and fruits immoderately. She returned to the anti-diabetic diet, and I found the urine free from sugar with all the diabetic symptoms relieved on August 2, 1881. She then returned to her old habits of eating, and the urine was found loaded with sugar on Sept. 27, and Oct. 29, 1881. I learned that she died "of diabetes," never having returned to the anti-diabetic diet, in Cuba, in 1882. During the last few weeks of her life she was much prostrated, suffering intensely with boils and carbuncles, which were probably the immediate cause of death.

The diet-table which follows is adapted to those who are able to provide themselves with any kind of food required without regard to cost rather than to persons of restricted pecuniary resources; but I have recognized the fact that those who are subjected to the anti-diabetic diet should secure every possible variety of food. In making this table, I have drawn largely from those already published, particularly the list of permissible articles given by Bouchardat, but, after many trials of the so-called anti-diabetic flours and bread, I have come to the conclusion, as I have already stated, that they are nearly all unreliable. I prefer to make patients abstain entirely from bread, or I allow the crust of half a French roll two or three times daily if I cannot eliminate bread altogether from the diet. The gluten-breads, so-called, are not only unreliable, but they soon become very distasteful. When ordinary bread is allowed, the physician knows, at least, about how much starch is taken.

APPENDIX.

DIET-TABLE.

BREAKFAST.—Oysters stewed, without milk or flour; clams stewed, without milk or flour.

Beefsteak, beefsteak with fried onions, broiled

chicken, mutton or lamb chops, kidneys, broiled, stewed, or deviled; tripe, pig's feet, game, ham, bacon, deviled turkey or chicken, sausage, corned-beef hash without potato, minced beef, turkey, chicken, or game, with poached eggs.

All kinds of fish, fish-roe, fish-balls, without potato.

Eggs cooked in any way except with flour or sugar, scrambled eggs with chipped smoked beef, picked salt cod-fish with eggs, omelets plain or with ham, with smoked beef, kidneys, asparagus-points, fine herbs, parsley, truffles, or mushrooms.

Radishes, cucumbers, water-cresses, butter, pot-cheese.

Tea or coffee, with a little cream and no sugar. (Glycerine may be used instead of sugar if desired.)

Light red wine for those who are in the habit of taking wine at breakfast.

LUNCH OR TEA.—Oysters or clams cooked in any way except with flour and milk, chicken, lobster, or any kind of salad except potato, fish of all kinds, chops, steaks, ham, tongue, eggs, crabs, or any kind of meat, head-cheese.

Red wine, dry sherry, or Bass's ale.

DINNER.—Raw oysters, raw clams.

Soups.—*Consommé* of beef, of veal, of chicken, or of turtle, *consommé* with asparagus-points, *consommé* with okra, ox-tail, turtle, terrapin, oyster or clam, without flour or milk; chowder, without milk or potatoes, mock turtle, mullagatawny, tomato, gumbo fillet.

Fish, etc.—All kinds of fish, lobsters, oysters, clams, terrapin, shrimps, crawfish, hard-shell crabs, soft-shell crabs. (No sauces containing flour or milk.)

Relishes.—Pickles, radishes, celery, sardines, anchovies, olives.

Meats.—All kinds of meat cooked in any way except with flour, all kinds of poultry without dressings containing bread or flour, calf's head, kidneys, sweet-breads, lamb-fries, ham, tongue, all kinds of game; veal, fowl, sweet-breads, etc., with currie but not thickened with flour. (*No liver.*)

Vegetables.—Truffles, lettuce, romaine, chiccory, endive, cucumbers, spinach, sorrel, beet-tops, cauliflower, cabbage, Brussels-sprouts, dandelions, tomatoes, radishes, oyster-plant, celery, onions, string-beans, water-cresses, asparagus, *artichauts*, Jerusalem artichokes, parsley, mushrooms, all kinds of herbs.

Substitutes for Sweets.—Peaches preserved in brandy without sugar, wine-jelly without sugar, *gelée au kirsch* without sugar, *omelette au rhum* without sugar, *omelette à la vanille* without sugar, *gelée au rhum* without sugar, *gelée au café* without sugar.

Miscellaneous.—Butter, cheese of all kinds, eggs cooked in all ways except with flour or sugar, sauces without sugar, milk, or flour.

Almonds, hazel-nuts, walnuts, cocoanuts.

Tea or coffee with a little cream and without sugar. (Glycerine may be used instead of sugar if desired.)

Moderately palatable ice-creams and wine-jellies may be made, sweetened with pure glycerine; but although these may be quite satisfactory for a time they soon become distasteful.

Alcoholic Beverages.—Claret, burgundy, dry sherry, Bass's ale or bitter beer. (No sweet wines.)

PROHIBITED.

Ordinary bread, cake, etc., made with flour, sugar, desserts made with flour or sugar, vegetables, except those mentioned above, sweet fruits.

SILICATE OF SODIUM BANDAGE.¹

BY EUGENE O. BARDWELL, M.D., MOLINE, ILL.

GENTLEMEN:—I have frequently conversed with physicians of ability, age and experience, who have never employed and consequently never appreciated the value of silicate of sodium bandage as a permanent dressing in fractures of the long-bones.

Silicate of sodium is a solution of silica and sodium carbonate, containing 20 parts of the former to 10 parts of the latter; it is of a syrupy consistence with a specific gravity of from 1,300 to 1,400; it is also called soluble glass or water glass; it possesses many advantages over starch, dextrine, or plaster of paris, in that it is more easily applied, is more uniform in thickness, is more cleanly, and last but not by any means least, it does not contract on drying as do the others. The mode of application is very simple and easy, a common roller bandage is first applied, the joints and bony prominences being protected by cotton; this is followed by another roller which is painted *in situ* with the solution by means of an ordinary flat varnish brush. Other rollers are applied and painted in the same manner until four or five thicknesses of bandage coated with the silicate are in position. This is usually sufficient, but if thought necessary, strips of the roller may be laid longitudinally between the bandages and coated likewise with the solution. Pieces of tin or zinc may be placed between the folds if thought expedient, but I have never required their aid, the bandage without them being very hard and stiff when dry, and effectually preventing the slightest movement of the fracture. The silicate commences to harden at once and is usually hard enough to cut in 24 hours, and if properly put on will keep the fracture in position from the time of application. In fracture of the arm, leg or thigh, the bandage should of course commence at the fingers or toes to avoid possible strangulation; with this precaution, any one who is fit to apply a roller at all, can use this preparation with perfect safety and without fear.

At the end of one day it is usually advisable to cut the roller, as it will probably not fit the part closely enough, as the equable pressure of an unyielding substance from the extremity to a point above the fracture will generally quiet muscular ac-

tion, and consequently, in removing a prominent source of irritation, reduce the swelling of the part affected. No one would think of using an application of this nature until the swelling and engorgement following the injury had perceptibly diminished. It is not, however, either necessary or desirable to wait until the swelling has entirely disappeared.

The bandage should usually be cut at the end of twenty-four hours. This may be done with Seuten's pliers, which are sold by dealers in surgical instruments. They are heavy shears with the blades curving upward, the nether blade being flattened to facilitate its introduction under the bandage. In lieu of these a narrow strip of tin or zinc may be placed along the limb under the first silicated layer, and with this for a director any strong cutting instrument may be utilized. Commencing at the extremity, the bandage is cut through from one end to the other, usually on the external aspect of the limb, for the sake of convenience. At distances which are variable, owing to circumstances, pieces of a roller or of tape are then passed around the bandage, or splint, as it is now more properly called, and tied firmly enough to hold the injured member in proper position. If the limb is smaller than when the bandage was applied, a longitudinal section is cut out wide enough to leave a small space between the edges of the splint when tightened, so that should it become looser in the absence of the surgeon it may be easily tightened with the tapes by the patient himself or any one in the household. In cases of compound fracture, a trap may be cut anywhere for purposes of drainage, examination or treatment. As a rule, we apply this dressing about the seventh day following the injury, and in ordinary cases the patient is able to be out of bed two or three days later, able to sit on a chair and get around on crutches with perfect comfort, so far as pain is concerned, and without any prejudicial effect on the union of the fracture. We are aware that a certain length of time must inevitably elapse after fracture before complete union can take place. The general health and physical condition of the patient will, however, as it is good or bad, shorten or lengthen this period perceptibly; and certainly the sooner the patient can get out of bed with perfect comfort and safety the sooner will his general condition approximate the normal. I think that the great majority of cases of fracture of the long bones, either simple or compound, can, with perfect safety to themselves and with gratification to their friends and their physician, get about the house in from ten to twelve days.

A few cases may be adduced in illustration. In the fall of 1879 I was sent for to see a man who had been injured by the fall of a building. I found his right tibia fractured at the lower third and his right ankle badly sprained, the fracture was reduced and the usual splints applied, it was six weeks before he could get around the house, and several months before he entirely recovered. About two months later W. H. while working in a saw mill, was caught by the carriage, thrown down and injured. On examination I found his right ankle severely sprained and the tibia of the corresponding side fractured at the

¹A paper read before the Rock Island County Medical Society at Rock Island, Ill., April 1, 1884. Published by request of the Society.

lower third, with an open wound leading to the fracture where the patient said the bolt entered which broke his leg; the fracture was reduced, the wound covered with a compress saturated with carbolized oil (1 to 40) and the limb kept in position by sand bags. At the end of six days, the swelling having materially diminished, I applied the silicated roller, cutting a trap over the wound, the next day I cut the bandage and put on the tapes. Three days later W. H. was out on crutches, said he had no pain, and the splint was left off entirely at the end of four weeks. These two cases under the same treatment would in all probability have followed the same course, although the latter, being compound, was the most serious.

In the spring of 1882 I was sent for to see a boy of 8 years, who had been injured by the fall of a pile of lumber. He had sustained a fracture of the right tibia at the middle third, the silicated bandage was applied the fifth day. I cut it the next day and showed the mother how to adjust the tapes to keep the splint tight enough, the boy got up that afternoon and I did not see him again until he walked into my office with his father five weeks later. In August, 1883, G. C., aged 50 years, working in a saw mill, received a blow from the end of a heavy plank which fractured the right femur at the junction of the middle with the lower third. I reduced the fracture and used extension to the amount of twelve pounds for four days, when it was reduced to eight pounds; the sixth day the silicated bandage was put on from the toes to the trochanters, the weights were left on until the roller became hard and were then removed, the splint opened, and tapes adjusted; careful measurement showed the leg to be the same length after the weights were removed as before.

The patient got about on crutches without pain or uneasiness at once, and at the end of two weeks walked on crutches one and one-half miles from his house to the mill, and returned the same afternoon without any bad results whatever; when I last saw him in October, he walked without a cane and without a limp. I have treated numerous other cases with this preparation, as have other physicians of my acquaintance, and the results have been uniformly successful and gratifying to all concerned. It is my belief that the great majority of cases of fracture of the leg and thigh should be out of bed within two weeks from the date of the injury, and that they may be with perfect safety to the injured member and with great benefit to the physical and mental condition of the patient. Of course there are cases where complications may exist or arise to prevent, but they will prove exceptions to the rule.

I have used the silicate in place of plaster of paris in the application of Sayre's jacket for spinal curvature, and believe it much to be preferred to the latter in every way. In conclusion I would request the members of this society who have not used this dressing to give it a trial before passing judgment. Those who have used it will, I am sure, endorse my statements.

MEDICAL PROGRESS.

MEDICINE.

M. PASTEUR ON THE VIRUS OF RABIES.—This important paper, which was communicated to the Paris Académie des Sciences, and which is exciting so much comment at present, is literally translated (*Medical Times*) as follows:

The important fact that certain infective poisons vary in respect to their virulence, and that insusceptibility to a virus may be secured by means of another virus of less intensity, is at the present moment not only an abstract scientific discovery, but has found an application in the domain of practice. Research being once turned in this direction, it is easy to understand how great an interest attaches to investigations into the methods of attenuation appropriate to new viruses. I have the honor, on the present occasion, to bring under the notice of the Academy an advance in this direction, in reference to rabies.

1. If the poison of rabies be transmitted from the dog to the monkey, and then from monkey to monkey, its virulence diminishes with each inoculation. If the virus, which has been thus enfeebled by inoculation from monkey to monkey, be then retransmitted to a dog, a rabbit, or a guinea-pig, it still remains attenuated. In other words, the virulence never returns at once to the degree found in the mad dog in the streets.

2. The virulence of the poison of rabies is increased when it is transmitted from rabbit to rabbit, or from guinea-pig to guinea-pig. When the virulence has thus increased and reached its maximum in the rabbit, the virus still retains this high degree of virulence when transmitted to the dog, and is evidently much more intensely virulent than the virus of the mad dog of the streets. Under these conditions, indeed, the poison is so virulent, that when inoculated into the circulation of a dog, fatal rabies is the invariable result.

3. Although the virulence of the poison is intensified in its passage from rabbit to rabbit, and from guinea-pig to guinea-pig, it requires many successive inoculations before it recovers its maximum virulence, when it has been previously attenuated in the monkey. Further, the poison found in the mad dog of the streets, which, as I have just said, is far from being of maximum virulence, when it is inoculated in the rabbit, requires to be passed through many individual rabbits before it attains that maximum.

If we apply rationally the results I have just communicated, we can easily render dogs proof against rabies. The investigator may have at his disposal the virus of rabies in different degrees of attenuation; the non-fatal kinds preserving the economy from the effects of the more active and fatal kinds. Let us take an example. We take the virus of rabies from a rabbit which has died after inoculation by trephining at the end of a period of incubation, exceeding by several days the shortest period of incubation commonly met with in the rabbit. This period invariably occurs between the seventh and eighth day

after inoculation by trephining with poison of maximum virulence. The virus from a rabbit, with the longest incubation period, is inoculated, again by trephining, in a second rabbit; the poison from this rabbit in a third. Each time the poison, which is becoming less and less virulent, is communicated to a dog. The latter is at length found capable of resisting a poison of fatal virulence. It becomes, in fact, entirely proof against rabies, when the poison of the mad dog of the streets is introduced into its system, either by intra-venous inoculation or by trephining.

By inoculations with the blood of animals I have been able greatly to simplify the operation of vaccination, and to produce in the dog the most marked insusceptibility to this disease. I shall shortly communicate to the Academy the total result of what I have found in connection with this point.

It will be of considerable interest, both now and up to the distant epoch when rabies has become extinct as the result of vaccination, to be able to prevent the disease developing after bites by rabid dogs. On this point the first experiments that I have made give me the greatest hopes of success. Thanks to the length of the period of incubation of rabies when communicated by the bite of a rabid animal, I have reason to believe that we can with certainty produce a condition of insusceptibility in those who are bitten, before the fatal malady is due.

The first results are very favorable to this view, but it will be necessary to repeat the experiments to an infinite extent on all manner of animals, before we shall have the courage to try this mode of prophylaxis on the human subject.

The Academy will understand that, in spite of the confidence inspired by the numerous experiments I have made during the last four years, it is not without apprehension that I now publish facts which point to nothing less than a possible prophylaxis against rabies.

If I had had sufficient material at my disposal, I should have preferred to defer this communication until I had asked some of my colleagues at this Academy and at the Academy of Medicine to examine the conclusions I have just made known. In deference to these scruples and motives, I took the liberty of writing a few days ago to Mr. Fallières, Minister of Public Instruction, asking him to be good enough to appoint a commission to whom I might submit the dogs which have been made proof against rabies. The crucial test which I would propose, would consist in the first place in taking from my kennels twenty dogs proof against rabies, and placing them side by side with twenty dogs intended to serve as my witnesses. We should then have these forty animals bitten successfully by mad dogs. If the facts which I have enumerated are correct, the twenty dogs which I believe to be proof against the disease would all remain healthy, while the twenty witness dogs would become infected with rabies. In a second and not less conclusive experiment, we should take forty dogs—twenty vaccinated before the Commission, and twenty not vaccinated. The forty dogs would then be inoculated by trephining with

the virus of the mad dog of the streets. The twenty vaccinated dogs would be proof against the infection, while the other twenty would all die of rabies, with symptoms either of paralysis or madness.

CASES OF EPILEPSY, WITH UNUSUALLY SLOW PULSE.
—At a recent meeting of the Harveian Society of London (*Medical Times*), Mr. St. George Mivart read the notes of a case of epileptiform convulsions in a retired policeman aged 61 years, which were of six years' standing—the pulse rate ranging now from 20 to 24 beats per minute. The convulsions were not frequent, the last being eight weeks previous. There was a slight systolic mitral murmur, together with an aortic systolic murmur. He considered the case to be one of fatty heart, with atheromatous deposit about the valves; and considered the seizures to be essentially of a syncopal character, modified by the epileptic tendency of the patient.

Dr. Hare related at some length a closely analogous case of unusually slow pulse associated with *petit-mal*. The pulse had gradually dropped to the unparalleled rate of $13\frac{1}{2}$ per minute, at which it was maintained for a considerable period, ultimately rising to 30 and 40. The patient, a nobleman, aged 57, had, up to the time of his illness, displayed the greatest activity, both mental and physical. Death occurred in a fit. No abnormality of the heart sounds had been observed during life, and at the *post-mortem* examination the valves were found competent, and the heart but slightly enlarged and not fatty—with the exception of slight enlargement of the kidneys, the other organs were practically normal.

ESBACH'S METHOD FOR ESTIMATING THE QUANTITY OF ALBUMEN IN URINE.—Dr. Henry Veale gives this method at some length in the *British Medical Journal*. The method consists in measuring in a graduated tube, the height of the deposit given by a measured quantity of albuminous urine, when treated with a solution containing picric acid and citric acid in the proportions respectively of one and two per cent.

The test tube is somewhat stouter than an ordinary test tube. It is six inches long, and about nine-sixteenths of an inch in diameter. On its outer surface it bears a scale of seven degrees, diminishing in size from below upwards, whereby the quantity of albumen represented by the deposit is intended to be read off in grammes per litre, *i. e.*, in parts per 1,000. Somewhat above this scale is a dotted line marked U (urine), and at a certain distance above it another line marked R. (re-agent).

The test solution is made by dissolving one part of picric acid and two parts of pure air-dried citric acid by the aid of heat, in about 80 or 90 parts of distilled water, adding subsequently enough water to make exactly 100 parts—or 35 grains of picric acid and 70 grains of citric acid in 8 fluid ounces of distilled water.

1. The urine should be filtered.
2. If not distinctly acid, it should be rendered so by the cautious addition of acetic acid, drop by drop, until it changes litmus paper to a brick-red.
3. If the specific gravity exceed 1010, the urine

should be diluted by one or more volumes of water, so as to bring it below that figure.

4. If, after the first trial, the urine should be found to contain more than 4 per 1,000 of albumen, it should be diluted so as to bring the deposit below the line 5 of the tube; and in either of these two cases the indication given by the deposit must be doubled or trebled according to the degree of dilution.

5. With the urine thus prepared, fill the tube up to the line U. Add the re-agent up to the line R. Close the tube with an india-rubber plug, and gently turn it up and down a dozen times, so as thoroughly to mix without frothing the contents.

6. Let the tube remain at rest in the upright position for twenty-four hours, and, at the end of that time, read on the scale the amount of the deposit.

Example—A patient passes in twenty-four hours in cubic centi-metres of urine— $35\frac{1}{4}$ fluid ounces of specific gravity 1024—a filtered portion of this is diluted with twice its bulk of water, and the deposit, after 24 hours, reaches to the line 3 of the tube. Then, this number multiplied by 3, on account of the dilution, indicates 9 grammes per litre (*i. e.*, 9 parts per 1,000) as the quantity of dry albumen contained in the specimen. Of course the same number divided by 10 will give the parts per hundred, and, if this be multiplied by the factor 4.4 (strictly 4.375) it will give, very nearly, the number of grains per fluid-ounce; thus, $9 \times 4.4 = 3.96$.

Dr. Veale finds Esbach's method to afford results that are accurate enough for all clinical purposes. It is simple enough to be performed as a daily duty by any intelligent nurse, or even by the patient himself. It is certainly better adapted for cases in which the loss of albumen is large, as in nephritis and certain cardiac diseases, than for those in which the albuminuria is slight and transitory; but, in the latter, a daily quantitative estimation of the albumen discharge would very seldom be considered requisite.

A THERMOSTATIC NURSE.—After the description of the couveuse which has been given in these pages, it will be well to refer to an English invention of somewhat the same character which is now in use in the City of London Lying-in Hospital, by Dr. Clement Godson. The apparatus, according to the *Lancet*, is made upon the same principle as the Champion Incubator for eggs, from which it differs in having a cradle above the water-tank instead of a drawer below. The case of the thermostatic nurse is of wood, and is divided horizontally into an upper and a lower compartment by a shallow enclosed tank of water, which extends to within two inches of the wood work all round, this interval being left to allow of the free access of air from the lower to the upper part. Above the water tank, and supported on slips of wood, is a cradle for the reception of the infant, which is kept in view through a glass window on the top of the apparatus. This sash is hinged at the back to a portion of the cover, about four inches wide. Affixed to this part of the cover is the lever-plate, the alarum, and the thermometer, the scale of the latter being outside and under immediate observation. Through the bottom of the apparatus a hole three inches in diameter

permits the entrance of a liberal supply of pure air, which constantly traverses two layers of very coarse canvas kept continuously wet. This is obtained by a simple arrangement of a metal tray with central perforated cap fitting over the opening in the bottom, and a coarsely-perforated zinc plate, coated on its upper surface by the canvas which dips into the water all round the edges of the tray. By this means the canvas is continually absorbing the moisture, while it is receiving a regular supply of heat from the bottom of the water-tank; thus the air entering is uniformly moistened and heated. Altogether outside the apparatus there is a gas flame, the heat from which passes through a flue shaped like the letter U, so as to traverse twice the length of the water-tank, by which means the water is heated. The great advantage of this apparatus, however, is seen in the automatic arrangement which it possesses for keeping the internal temperature uniform. A hermetically-sealed metallic capsule, two inches square and containing a small quantity of a liquid which boils at 90° F., is fixed in the space at the head of the cradle; and in the center of the upper part of this capsule is a button, having a cup-shaped depression, in which rests the lower end of a stiff wire, which passes out through the top of the apparatus, where it comes into contact with a light lever, which is pivoted to a brass plate. From the free end of this lever hangs a little damper, which rests on the top of the chimney under which the gas-jet burns. As soon as the temperature in the infant's room reaches 90° F. the liquid in the capsule will boil, and the vapor thus produced converts the flat capsule into a rounded one, thereby raising the rod, which, acting on the lever, at once lifts the damper off the chimney, allowing the heat from the flame to escape by that outlet, and preventing the further heating of the water-tank. If a higher temperature than the boiling point of the liquid within the capsule be desired, this can be obtained by moving a weight along the lever toward the end to which the damper is attached; the further it is placed in this direction, the greater is the heat produced. The alarm is made to ring whenever the internal temperature reaches a certain point. It should be mentioned that outside the machine, near the foot of the cradle, a feeding-cup is placed, the food within which is kept warm and ready for use by means of the hot water in the tank.

MEASUREMENTS OF THE SPECIFIC GRAVITY OF THE BLOOD IN DISEASE.—Dr. Charles S. Roy gives to the Physiological Society the following method for this purpose (*The Journal of Physiology*): The abandonment of venesections has caused a neglect of this interesting and important subject, as it is no longer an easy matter to obtain from the living patient a sufficient quantity of blood to permit of its density being estimated by any of the various methods which are in use for measuring the specific gravity of fluids.

The few observations which are recorded on the density of the blood in disease show that the specific gravity of this fluid may undergo very great changes as a result of various morbid conditions. Davy, for example, gives one case in which the density of the

blood was found so low as 1038—the normal average in man being 1055.

The only instrument required for measuring the specific gravity of the blood by Dr. Roy's method is an ordinary hypodermic syringe, the needle of which has been slightly altered, its point having been taken off and the steel tube prolonged backwards so that its inner end when it is fixed on the syringe is visible from without. Besides this instrument there are required a number of solutions of salt of various densities from 1040 to 1075. Two dozen ten ounce bottles are amply sufficient, they should be wide enough in the mouth to allow of the syringe being filled from them directly.

The syringe having been half or three-quarters filled with one of the salt solutions, a portion of a drop of the blood to be examined (obtained from the finger in the ordinary way) is drawn up into the syringe, care being taken that no air is introduced with it. If, now, the blood be of greater specific gravity than the fluid in the syringe, it at once sinks to the lower part of the latter, while if it be of less density, it at once rises to the upper part of the glass tube of the syringe. In the former case, having emptied the syringe, the process is repeated with a solution of higher specific gravity, and one or two trials enable the observer to find between what two solutions the drop of blood ceases to sink and rises instead. The method is one of extreme delicacy, a very minute difference in density between the blood and the fluid employed showing itself at once by the behavior of the drop.

The difference in temperature between the blood and the standard solution into which it is drawn, might seem to have a marked influence on the result of the measurement. The effect of this is found, however, in practice to be so slight that it may, for all practical purposes, be ignored. This is doubtless due to the fact that the small part of a drop which is drawn into the syringe, at once loses a great part of its heat to the much larger quantity of fluid with which it comes in immediate contact.

The following is briefly all that is known on the subject of the normal limits of the density of blood in man:

The blood of men is somewhat heavier than that of women, the values for the former being from 1056 to 1059, while the blood of females varies from 1051 to 1055. The blood of children is specifically lighter than that of adults. It would also seem that the density of the blood is greater in the morning than it is at night, an effect apparently due to the fluids swallowed during the day.

ANATOMY AND PHYSIOLOGY.

FUNCTIONS OF THE SPLEEN.—In the last number of *Virchow's Archiv*, Professor Alex. Tauber, of Warsaw, gives as quoted by the *Lancet*, an excellent review of the theories concerning the functions of the spleen, closing with the results of his own observations.

Thus, in 1833 Tiedemann considered the spleen to be a blood-forming organ, and that after its removal its function was transferred to the thyroid body; an opinion contested by Brücke, who held there was nothing in common between the thyroid and the lymphatic system, to which the spleen belonged. Neumann and Ehrlich doubt that the spleen has any hæmopoietic function. Schiff and Herzen think that the spleen develops a ferment which is necessary to the pancreas in its digestive action, a view disproved by the fact that nutrition is not impaired by removal of the spleen. Schiff goes further by asserting that its removal does not influence, either actually or relatively, the amount of red and white corpuscles, whilst Robin, on the other hand, found in two cases of splenic extirpation in the human subject an increase in the number of leucocytes, and notable variations in the size of the corpuscles. Recently Winogradaff, of St. Petersburg, found very marked changes in the lymphatic glands, and also in the bone-marrow of animals deprived of the spleen, the former being softer than normal, and containing many free red blood-corpuscles. At the German Surgical Congress, held at Dresden in 1882, Dr. Crédé showed a man forty-four years of age, from whom he had successfully removed a cystic spleen. Two months after the operation the blood was found to contain a large excess of leucocytes, but three months later their number was nearly normal. Crédé had observed in the early weeks after the excision that the thyroid had enlarged in size—an enlargement which persisted to a certain extent. The lymphatic glands did not enlarge. Crédé concluded from this and other cases that the splenic function was to convert white into red corpuscles, and that leucocytosis ensues on removal of the organ until the thyroid is enabled to act vicariously.

This idea was further expanded by Zesas, who published the details of experiments on the subject at the end of 1882, from which he concluded that the spleen converted white into red corpuscles, but that other organs also had this power; that increase in the number of white corpuscles and diminution in the red occur upon extirpation of the spleen until the above function is taken on by another organ, and that this property of acting vicariously to the spleen resides in the thyroid as well as in the bronchial and mesenteric glands. The lymphatic glands alone are incapable of supplying the needs of the organism in this respect, so that simultaneous removal of the spleen and thyroid is incompatible with life, this last being based on the issue of a single experiment.

Tauber remarks that practical surgery now affords more means of arriving at a conclusion, since more than fifty cases of extirpation of the spleen are on record. In 1882, previous to performing this operation for cystic degeneration of the organ, he made many experiments on the lower animals, and was thereby convinced that excision of the healthy spleen could be performed without injury to the animal's health. He practiced excisions of the spleen and of the thyroid in fifteen animals, in some removing one of these organs, in others both, and examined

the blood in each case. Six of these animals died, one from the operation itself, another from acute peritonitis; the others from weakness within three weeks of the operation, after the wounds had cicatrized; post-mortem examination showing marked congestion of the liver, lungs, and lymphatic glands, and intestinal hæmorrhages. He points out that the thyroid is very often entirely wanting in the domestic animals, and yet in such animals splenectomy is as well borne as in those having a well developed thyroid. These experiments then do not support the doctrines advanced by Tiedemann, Crede, and Zesas as to an interchange of function between these organs. Nor did Røeher in his numerous cases of thyroid excision in the human subject meet with one case in which the spleen became subsequently enlarged.

The deductions Tauber draws from these experiments, and from clinical observations, are: 1. That the spleen must be regarded as one of the main reservoirs of the blood; its removal, therefore, exerts a great influence on the circulation, as seen in the occurrence, shortly after the excision, of congestion of the liver, kidneys, and especially of the lymphatic glands. 2. No physiological affinity exists between the thyroid and the spleen. 3. An animal of middle age bears splenotomy much better than an old animal, hæmorrhages being liable to occur in the latter. 4. Animals deprived of the spleen can bear living young, in whom the spleen is present. 5. The removal of the spleen does not impair the digestive function or nutrition. 6. After removal of the spleen the animal becomes anæmic; the relative and positive number of white corpuscles notably increases, whilst the size and number of the red corpuscles diminish.

SURGERY.

AN EASY AND SAFE METHOD OF SOUNDING FOR IMPACTED GALL-STONES.—With this title as its heading, Dr. George Harley communicated a paper to the Royal Medical and Chirurgical Society (*Medical Times*) which contained the details of the case of a lady 36 years of age, who had been for many weeks suffering from the signs and symptoms of obstructed bile duct. After placing her under an anæsthetic, Dr. Harley inserted a six-inch long French exploring trocar midway between the umbilicus and margin of the liver, an inch and a half to the right of the median line. Its point being pushed upwards and backwards in the direction of the common bile duct, no hard substance was met with; on the stilette being withdrawn ascitic fluid came away, and the canula could be moved freely in all directions. The instrument was withdrawn and re-inserted an inch higher up, and about two inches to the right of the umbilicus. On pushing it in the same direction as before, to the depth of six inches, its point struck into a hard substance, presumed to be a biliary calculus. It was endeavored to estimate the size of the

stone by pressing the end of the canula without the stilette firmly against the hard substance, and moving the point of the instrument all round it. The inference was that the stone was the size of a hazel-nut. The punctures were closed by means of sticking-plaster, and the abdomen bandaged. The signs of obstruction began rapidly to disappear, and it was supposed that the operation had caused the stone to change its position in the duct, and had thus enabled it to pass along into the duodenum. Convalescence at once set in, but was of short duration, for an attack of enteritis supervened, followed by peritonitis, and the patient succumbed twenty-seven days after the sounding, and twenty-four after the stone had evidently left the duct. At the autopsy, the thirteen calculi shown to the Society were found still in the gall-bladder, the longest being an inch in length, the next the size of a hazel-nut, the remainder all much smaller. The facets on the opposite ends of the large calculus showed that another stone, the size of a hazel-nut, must have existed, but come away. The paper ended with the following conclusions:

(a). That the presence of an impacted gall-stone may be readily, as well as safely, ascertained in the way described.

(b). That not only the position, but even the size and shape of an impacted biliary calculus may be instrumentally ascertained.

(c). That a knowledge of these facts may possibly induce surgeons to undertake the earlier artificial removal of dangerously impacted gall-stones than heretofore; an operation which ought to be, under ordinary circumstances, no more hazardous to the life of the patient than the operation of lithotomy. He believed that the fatality that had hitherto attended the operation had been almost entirely due to the fact of its having been delayed until the exhaustion of the patient precluded the possibility of recovery.

In the discussion which followed the reading of this paper, the members present seemed to think the operation anything but an easy or safe one, judging from the views expressed by Sir William MacCormac, Dr. Dyce Duckworth, Dr. O'Connor, and Dr. C. J. Hare.

THERAPEUTICS AND MATERIA MEDICA.

MENTHOL.—Mr. Archibald D. Macdonald, in a note to the *British Medical Journal*, calls attention to the fact that he was the first to point out the antiseptic and anti-neuralgic properties of menthol, in the *Lancet*, in 1879. He uses this drug in tinea tonsurans with success, both simply in rectified spirit, and in a pomade with iodoform and vaseline.

In facial neuralgia, some forms of sciatica, neuralgic headache (clams), and in toothache, he has repeatedly given relief by its use, both in the form of the stick or cone, and with the following formula—menthol, 30 grains; spirit of rosemary and rectified spirit, each 2 drachms.

BLINDNESS FROM OPHTHALMIA NEONATORUM AND ITS PROPHYLAXIS.—The possibility of blindness occurring to a human being from any cause whatever, and at any period of life, is of such vital importance to everyone concerned that it is not possible to give too much attention to avert such a possible danger. This is especially the case where any neglect of the helpless infant, when ushered into the world, may involve the absolute deprivation of the sense of light for a whole life-time. That many have been in the past, guilty of such neglect, is manifest from the testimony afforded by the statistics of the victims to a life-long blindness. Magnus,¹ of Breslau, gave as his observation up to the time referred to, that 34 per cent. of the blind in the institution at Breslau became blind as a result of ophthalmia neonatorum. He has, however, in his recently published work *Die Blindheit, ihre Entstehung und ihre Verhütung*, reduced, by further observation, the percentage to 13.25 per cent., whilst the percentage of the aggregate of a number of observers in different parts of the German Empire amounts to 10,876 per cent. Calling this number for the sake of convenience 10, we have the astonishing statement that 10 per cent. of all the blind, that is totally blind, in Germany, have been thus deprived of sight through ophthalmia neonatorum. This it must be remembered takes no cognizance of those cases where the sight has been only more or less impaired. We have not at hand the necessary statistics to enable us to form an opinion as to whether an equally alarming result

would be furnished by our own institutions; but from the figures at our disposal it is probable that an equal number of victims which swell the ranks of the blind in our own country are from the same cause deprived of sight. And they are consequently not only practically deprived of contributing to the world's wealth, but dependent on the contributions of others. It is well, in order to form an adequate conception of what these figures mean, to refer to the figures of Dr. Appia as quoted by Magnus. He states that France spends nine million francs a year for the support of the blind, and if 10 per cent. of this is caused by ophthalmia neonatorum, we have an expense of nine hundred thousand francs for the sustenance of those suffering from this affection alone. According to the calculation of Magnus, the whole cost to Prussia of its blind is twenty million marks a year, and making a similar allowance of 10 per cent. of ophthalmia neonatorum, we have an annual sum of two million marks entailed on the government by this affection alone.

We have only referred to this economical aspect of the question, however, in order to bring into relief the magnitude of the question under consideration. No physician needs such a reminder to induce him to discharge his duty. If the ambition of doing all that he can do for a given case and doing it well, is not an inducement strong enough, no question of economy will supply the necessary zeal. As a matter of fact this 10 per cent. of blind from ophthalmia neonatorum, as shown by the observations of Credé at Leipzig, is simply the result of negligence or ignorance which, by due care, can be completely avoided. We cannot by this be understood as saying that no case of ophthalmia neonatorum needs be followed by the loss of an eye, but we do say that no case should be allowed to get into that condition where such a result is unavoidable. Care should be taken as early as possible after delivery to have the child's eyes washed with clean water and a little soft linen or a wad of absorbent cotton, each piece when it has been used being thrown away to give place to a piece unsoiled. Should any suspicious accumulation be seen, however, in the region of the eyes it should be carefully wiped off before the process of washing takes place. It should not be necessary to remind those who undertake such a duty that whatever there is objectionable in the parturient canal will be sure to find a lodgement in the angles of the eyes, and consequently no one can claim to have given cleanliness a fair show who has not given special attention to these regions. Successful efforts have been directed by Professor Credé,

¹Breslauer Arzliche Zeitschrift, 1882, No. 19.

of Leipzig, to the prophylaxis of this affection and the admirable results which he has obtained, convinces one that if the 10 or 11 per cent. of the blind attributable to ophthalmia neonatorum, continue to figure in our statistics of the blind, it will be because the little ones have been ignorantly or negligently attended to.

The records¹ of the Leipzig lying-in hospital from the beginning of the year 1874 to the end of May, 1880, show that 10 per cent. of all the births there developed ophthalmia neonatorum, whilst after special attention was given to the infants' eyes, the number was reduced to one-half of one per cent., in fact an individual case, which it was found had not received proper attention. The plan there adopted is such as we have referred to with the addition of a single drop of a 2 per cent. solution of nitrate of silver, which is dropped from a glass rod on to the cornea. Although we should prefer to depend on cleanliness alone, reserving the solution of nitrate of silver for the manifestation of active difficulty, yet it would appear from the observations of others that the same advantage is not obtained from simple cleanliness, so that whenever it is known that a leucorrhœal discharge exists at the time of delivery the most efficient prophylactic measures consist in supplementing the most scrupulous cleanliness with the instillation of a single drop of nitrate of silver into each eye. This seems the more plausible, as Professor Credé assures us that no evil consequences whatever associated with its application. Children born at full term exhibit merely a slight redness, never any swelling, whilst in children of premature birth a slight increase of secretion is developed, which disappears at the latest at the end of forty-eight hours. He claims that after the instillation of the nitrate of silver no further attention is necessary.

The probability is, however, that the greater part of the cases of ophthalmia neonatorum occur in the hands of midwives, consequently any prophylactic measures should be of such a nature that the midwives can readily be trusted with them. Now a 2 per cent. or a 10 grain to the ounce, solution of nitrate of silver, can scarcely be entrusted to the average midwife for instillation into the eye of an infant, consequently we should prefer to trust to a scrupulous cleanliness early effected, and consider the question of nitrate of silver later on if the disease displays itself. This position is justified by the teaching of both ophthalmologists and by those who devote their attention especially to gonorrhœa. Both specialists

tell us that active agents in the early stage of the disease are to be avoided.

PROGRESS OF CHOLERA IN FRANCE.—The chances of controlling the epidemic within the cities of Toulon and Marseilles are by no means as hopeful as they were a week ago. The number of cases has steadily increased in those cities, and the disease is appearing at other points. Quoting from the dispatches of this morning, July 8, we find that night before last there were sixteen fatal cases in Marseilles, and during yesterday up to five o'clock there were twelve.

At Toulon during the same night there were nine deaths, and during yesterday there were seven.

Two cases were reported yesterday at Nice. Eighteen hundred persons left Marseilles yesterday.

An English steamer from Marseilles was signalled off Lisbon July 6, having two cases of cholera on board.

Two refugees from Toulon were found at Saluzzo the same day, victims of cholera.

Dr. Koch, of the German Cholera Commission, is busy at Toulon making examinations of cholera patients. He states that the epidemic is Asiatic, and finds *microbes* of the same class as in Egypt and India.

He predicts a general spreading of the disease from so central a point as Toulon.

Such are the commercial relations of Great Britain with France that it seems well nigh impossible to establish the absolute quarantine which was established in Egypt last year, and we may look for the appearance of the disease along the great centers of travel, as a matter beyond control.

We again urge all who may in any way be responsible for the sanitation of the highways of travel and the health of cities to leave no effort untried which shall promise restraint to the spread of the epidemic or which may lessen its fatality.

The popular germ theories and associate doctrines of contagiousness, greatly exaggerated by the newspaper press, are adding to the terror of all classes of people, and will correspondingly increase the destructive effects of the epidemic wherever it makes its appearance. For of all the predisposing causes of cholera, fear, dread, and mental trepidation are among the most efficient. While cleanliness of person and premises, wholesomeness of diet, and a fearless contented mind, usefully occupied, will do more to protect the individual in the midst of a cholera epidemic than all other prophylactics put together.

CHOLERA GERMS AND CHOLERA VIRUS.—It is well known that Prof. Koch, in his communications to the

¹ Magnus, die Blindheit, etc., p. 300.

German Government, claims as the result of the investigations of his commission, both in Egypt and India, the discovery of a bacillus which is specifically essential to cholera, and readily found in every case, in the mucous membrane of the intestines and in the rice-water stools. It is also stated that the same variety of bacillus was found in some of the water used by the natives in India.

Koch states that these bacilli are peculiar as to shape, motion, and tendency to aggregation.

He does not believe them to be simply concomitants of disease, or normal intestinal inhabitants.

They are not found in the stomach or matters vomited, which were not obviously of fæculent character.

He has thus far failed to inoculate animals with these bacilli. They may be developed rapidly outside the human body when subject to warmth and moisture. They are readily destroyed by drying, and by contact with fluids even slightly acid. Alkaline solutions are not thus destructive. A field for further investigation is here opened, which, whether confirmatory or corrective of the views of Prof. Koch, can hardly be over-estimated in importance and its wide-reaching relations.

But while Koch has failed to propagate the cholera in any of the lower animals, either by inoculating them with his cultivated bacilli, or feeding them with the intestines of cholera patients, Mr. Vincent Richards, of India, has been more successful in his experiments on pigs, as the following extract from the *London Lancet* of May 10 will show:

"The *Indian Medical Gazette*, for April, contains a paper by Mr. Vincent Richards, detailing his experiments on pigs, which, as stated last week, were at first erroneously thought to be confirmatory of the opinion of Koch, that a bacillus is the essential agent in propagating the disease. Mr. Richards, who had previously failed in obtaining results in the dog, tells how he was led to administer choleraic discharge to pigs. A young animal so treated was attacked with vomiting, and died in a few hours. Another pig was fed on the contents of the intestines of a pig killed by the choleraic discharge, and remained unaffected; it also was not affected by the alvine discharge from a patient in the first stage of cholera, but was subsequently killed in eighty minutes by the administration of an undoubted choleraic evacuation. Decomposing choleraic discharges had no effect on the pigs; but, as in other instances, the administration of recently-passed stools proved more or less rapidly fatal, with symptoms of asphyxia. Mr. Richards concludes that the alvine discharges at certain stages of cholera contain a powerful poison, whose chief action is to enfeeble and destroy the function of respiration. The rapidity of its action excludes it from being an organism, and he thinks that it is a chemical com-

pound, probably of albuminoid nature. It remains for chemistry to isolate the body, and for experiment to determine accurately its physiological action; but Mr. Richards thinks that it will probably be found to be easy to disinfect the evacuations by permanganate of potash. He admits that, although the poison decomposes, it might, by desiccation, retain its powers for some considerable time, so that clothes, etc., stained with choleraic discharges might be a source of danger."

From the above statement it is apparent that Dr. Vincent Richards conceives that the poison of cholera is of a *chemical* character, and his experiments were instituted with the view of isolating this virus, and communicating it to animals successively, but not, like Koch, searching for a cholera bacillus.

If epidemic cholera is essentially dependent for its existence and propagation, upon a peculiar bacillus, which can be easily destroyed by weak acid liquids, as stated by Koch, it would seem as though it might be easily cured if treated by acids in the early stage of the attack, and its spread more effectually prevented by disinfecting the discharges with acid disinfectants, than by armed sanitary cordons. Yet both have been tried many times, in epidemics of former years, with results by no means uniformly successful.

BRITISH MEDICAL ASSOCIATION.—The fifty-second Annual Meeting of this Association, will be held in Belfast, on Tuesday, Wednesday, Thursday and Friday, July 29 to August 1, 1884. Local Secretary, John Moore, M.D., 2 Carlisle Terrace, Belfast.

SOCIETY PROCEEDINGS.

WARNING TO THE MEDICAL PRACTITIONERS IN REGARD TO THE USE OF JEQUIRITY.

BY M. LANDESBURG, M.D.

Read before the Philadelphia County Medical Society, May 21, 1884.

The medical journals have not failed to inform their readers that a new remedy has been introduced by Wecker into the oculistic therapeutics, which, by its prompt, energetic and sure action in trachoma and pannus, by far surpasses all the other methods of treatment ordinarily used in this affection. These glad tidings have been corroborated by the casual publication of notes and comments on the many excellent results obtained by Wecker and his followers by the new procedure, which consists of applying an infusion of jequirity, of a given strength, to the surface of the palpebral conjunctiva, in order to produce

rapid suppuration, and by means of the latter to promote absorption of the trachomatous infiltration. The method of treatment is based upon the same idea which led to inoculation of blennorrhæic pus in cases of pannus. I have not seen any medical paper at my command dwelling upon the great dangers in which the diseased eye is apt to be involved by the process of suppuration, and by the possible excess of reaction. I have not seen pointed out the fatal consequences which may develop in some instances. The glittering side of the question has only been made conspicuous, and it has not been considered worth while to show also the reverse of the medal. That this sin of omission may prove a source of trouble and mischief to some medical practitioners is obvious. The general physician is not in the position to follow all the intricacies of the experiments with the new drug. He relies for information on his medical journal, and the latter tells him of jequirity as the panacea in trachoma and pannus. Now suppose he just has such a case under hand, which had proved rebellious to the treatment with the usual remedies. He finds jequirity highly spoken of in his journal, and he avails himself of the opportunity to win by easy means the battle and the honors connected with it. And now it happens that he makes matters worse, that the very existence of the organ is endangered by the new treatment, the full recovery of which he has expected with such confidence! But I do not draw the picture from imagination; I do not speak of possibilities, but of facts that have already occurred. I relate incidents of the practical life which were communicated to me by general practitioners from different parts of our country. There was excess of reaction in some instances, and implication of the cornea in others. Besides, I have received letters in which physicians appealed to me for information concerning the action of jequirity and the expediency of using it in trachoma and pannus, urging me at the same time to lay before the profession the results of my experiments in the matter.

In answer to the many queries, by which I feel deeply honored, I have only to state briefly as follows:—

I have not had any cause to abandon my usual method of treatment in instances of trachoma and pannus, which has still given me the most satisfactory results even in the most obstinate and inveterate cases. My interest in jequirity has thus far been merely theoretical, and the successes reported from one side, and the failures brought forward by the other, have only served to uphold my position of objective observation. The question is by no means ripe for verdict. Only the future can show whether jequirity will gain a permanent place in the oculistic therapeutics, or will share the fate of the many other "new remedies," to sink into well-merited oblivion after a short period of dubious fame.

But if I cannot produce the results of my own trials with the use of jequirity in trachoma and pannus, I am able to give my experiences on the action of jequirity, which I have gained from experiments made by others. The issue of these experiments in nine cases, which came under my observation, indi-

cates plainly enough the course the general practitioner has to take in regard to jequirity.

Of the nine cases above mentioned, the result of the treatment with jequirity was negative in five cases of trachoma and pannus. There was no improvement whatever, but no injury done either. Two cases presented with trachoma and pannus, deep corneal ulcerations, which were asserted to have developed during the treatment with jequirity. Before the latter had been started, the patient had enjoyed fair vision. One patient, with xerophthalmus of both eyes, suffered the loss of the right eye in consequence of panophthalmitis, which had set in on the fourth day after the application of jequirity. There was not the slightest improvement in the left eye. A girl who had done nothing for her eyes up to the time of the treatment with jequirity, presented herself six weeks later with the following conditions: Lids thickened; palpebral conjunctiva intensely swollen, covered thickly with large granulations, and furrowed with tendinous cicatrices. Both corneæ opaque and vascular.

GYNÆCOLOGICAL SOCIETY OF BOSTON.

Stated meetings, Nov. and Dec., 1883. Wm. G. Wheeler, M.D., President, in the Chair; W. O. Hunt, M.D., Secretary *pro tem*.

(Nov.) A. P. Weeks, M.D., gave a detailed account of a case of *Acute Inversion of the Uterus*, which had occurred in his practice, followed by an essay, statistical and otherwise, upon the same subject.

Mrs. M., aet. 22, primipara, gave birth to a child at full term, in which, however, on account of ineffectual pains, the assistance of the forceps was required. A competent nurse rendered efficient help. After the birth, it was observed, that the ordinary globular tumor, which the evacuated uterus forms in the hypogastrium, was becoming less firm and distinct, a digital examination discovered the placenta in the vagina; upon this, a brisk hæmorrhage set in. Renewed investigations made it evident that the uterus had inverted. The whole hand was at once carried into the vagina, grasping and compressing the fundus, meanwhile that the left hand supported the abdomen. Thus reduction was completely accomplished and with but little loss of time. The hand was retained in the cavity and ergot and ice employed until firm contraction took place. Patient made a rapid recovery.

The reader considered this a typical case, unattended with the usual complications of a rapid delivery, a short funis, traction of the cord, irregular compression of the fundus, or undue bearing-down efforts on the part of the patient, conditions which are regarded as the ordinary factors of the accident.

A condensed report of 25 cases followed; 6 occurred in primiparæ, 8 in multiparæ, others unknown; a physician was in attendance in 14, midwife in 7; traction of the funis in 6 cases; compression of abdomen, slight, in 1; no force applied as factor in 14; placenta adherent in 14; non-adherent

in 11; os contracted in one, dilated in 8; uterus firm in 6, flabby in 5; inversion reduced in 21, non-reduced in 4; recovered, 20; died, 5; one case occurred at 2 months, two at 4, and two at 6 months. A careful analysis shows that inversion is about equally liable to occur in primiparæ and in multiparæ; that the strong are victims of the accident as well as the weak; that it both complicates rapid deliveries and long, tedious labors; that it occurs alike in the hands of experienced physicians and of incompetent midwives; that traction and compression in delivery of the placenta, figure but slightly as determining causes; that it matters not whether the placenta is adherent or non-adherent.

Furthermore, we find that of these 25 cases, 17 occurred immediately, or within one half-hour after the birth of the child; but in only 9 of the 17 was the inversion discovered at once; as respects the former class, the interval of non-recognition varied from 2 hours to 3 days. Of the nine that were immediately recognized—of which only 4 were reduced at once—the remainder went unreduced, respectively, 4, 10, 11, 12 and 15 days, and when we say immediately, of the other four cases, we still allow a period of 1 to 7 hours. The mortality is great, being 23.05 p. c., the greater portion dying of shock, a few of hæmorrhage, and still a few of subsequent inflammation.

The treatment consists of immediate reduction; if the placenta be attached it should be separated and removed first of all, as thus the hæmorrhage is slight and the danger of mortality less.

The President, remarking upon this paper, recalled but three cases that he had seen in forty years' practice—one was his own, the others he had encountered in consultation. Considered it especially necessary to recognize the complication at the time of its occurrence. Believed the cervix fails to do its duty and, relaxing while the rest of the organ is contracting, the uterus is forced through. Did not believe the accident due either to traction on the cord or external pressure.

Dr. Marcy believed that faulty innervation might serve as an important element.

Dr. W. S. Brown, in all his experience, had never seen a case. Was surprised to learn it could occur at two months. Was always accustomed to use traction upon the cord.

Dr. Clark recalled a partial case seen with a midwife; child born, flooding, placenta attached; felt a cup-shaped depression at fundus, easily reduced. The midwife had used great external pressure and the labor had been very rapid.

Dr. Wheeler still believed his two cases due to inertia of the cervix; in the second case the fundus was wholly outside of the genitals, severe shock, no flooding. Had to keep his hand in position, after return of the organ, for two hours before he could get sufficient contraction, in the meantime using ice, ergot, alcohol, etc.

Dr. M. L. Brown had had a case within the past week. Child born before he entered the house, and husband said all was right, but he found the patient cold, nearly pulseless, forehead wet and cold—in a

word, in a state of collapse. Upon vaginal examination, found cervix relaxed and fundus presenting in vagina, its projecting surface being firm and of wrinkled feel; reduction easily accomplished; no further trouble.

Dr. Church had often encountered inversion in the lower animals, in the mare, cow and sow; considered the cause an imperfect "make-up" of the animal.

Dr. R. L. Loring, corresponding member, agreed with previous speaker that traction was not a cause; Karl Braun uses traction and pressure; Mathews Duncan traces the accident to relaxation of the fundus which, being crowded down, is seized by the cervix like a child's head and extruded. Himself was disposed to look further and would suggest a possible unequal distribution of force in the uterine muscles, resulting in abnormal expulsive power.

Dr. Weeks responded and closed the discussion. Playfair imputes the fault to the accoucheur, while *per cont.* Sir Jas. Y. Simpson believed the condition beyond his control. Emmet attributes to too rapid delivery, to traction, pressure, assuming too soon the upright position. Lusk is positive that rapid delivery has but little to do with it.

Society adjourned.

Stated meeting, 2nd Thursday, December. President Wheeler in the chair, Henry M. Field, M.D., Secretary.

The chair announced the death of Dr. Marion Sims, of New York, an early and highly honored honorary member, and Drs. Warner, Marcy and Field were appointed a committee to prepare a proper memorial and present at the next meeting.

Henry A. Martin, M.D., read by appointment a paper on Listerism.

He began with a distinction between the germ theory and antiseptic surgery thereupon based, and Listerism. In the former he had his degree of confidence; the latter he regarded as one of the latest prevailing medical fashions and he had little respect for it.

Listerism, in its inception, had performed its service for the profession and the world—this he would not under-rate. It had converted many a former "murder-pen" of Europe into the modern cleanly and well-appointed hospital; it had substituted cleanliness and purity for dirt. On the other hand, it requires too frequent interference with the wound; and this is a grave fault in its method.

But, calling attention to what was before very generally known and only waiting to be put into operation, would never make a man famous. To bring fame it needed that a peculiar and largely absurd theory should be superadded; and it is this theory which chiefly constitutes Listerism. That Prof. Lister is earnest, and true, and honest, he did not doubt for a moment; but he did not see the inconsistencies which were presented to other minds which did not embrace his system; Hahnemann could never see anything calculated to upset his theories.

It has been proved that at a certain stage of animal decomposition a poison is developed, virulent and septic, which at a later stage seems to decompose

or consume itself and become innocuous. The reader showed at length and with force that this observation could not be made consistent with Listerian theories.

The former method with perforating wounds of the chest was to seal hermetically either opening; and the patient died under the treatment. Now that the wound is left open at both ends, kept clean, and effective drainage provided, the patient has a chance of recovery; no germicides are needed.

According to Prof. Lister, wounds ought to do very badly in a malarial atmosphere where the air must literally pullulate with bacteriæ; but, as matter of fact, wounds thus circumstanced do as well as elsewhere.

Again, observation of the relation of many of the so-called nuisances of the present day, both to public health and especially to the health of those who are directly engaged, *i. e.*, the employes, does not support Prof. Lister's theories. A certain suburb of Paris is devoted to the preparation of sewerage and excrementitious matters for agricultural purposes—such material being exposed to heat and other cicatrizing influences. The resulting smell is constant, intense, horrible; but wounds contracted in this pursuit do better, as a rule, than they do in Paris. Cholera did not invade this region at all upon occasions of late epidemics. A man named Ward set up a somewhat similar business some years ago in a portion of Roxbury; he was repeatedly complained of, most disastrous effects to the public health were freely predicted, and such apprehensions shared by almost everyone, physicians included; but he had hold of a good thing, was making money rapidly, and successfully resisted all efforts to disengage him—chiefly, however, because it could never be proved that the business had anything unhealthy about it. So with soap-boiling factories, where highly rancid fats are subjected to heat; the air does not appear to be vitiated so far as public health is concerned, and wounds contracted, by those engaged in the work, heal as well and as rapidly as under more pleasant circumstances.

In erysipelas, there is said to be a special or specific bacillus; but this Dr. M. very much doubted, because he had been able so often to cure the disease by means of no other agency than simply the rubber-bandage. A distinction should be made between erysipelas and simple erythema; the latter is the commonest occurrence after vaccination, and too often is diagnosticated as erysipelas. A pathognomonic condition of the latter is the presence of vesicles or blots; an erythematous eruption or blush, unaccompanied by this characteristic symptom, cannot properly be called erysipelas.

Dr. Martin was occupied in his argument close up to the hour of adjournment, the main features of which have been given in this abstract.

Society adjourned.

CHICAGO MEDICAL SOCIETY.

Regular meeting, held June 16, 1884.

The following paper, essay, and reports of cases were presented: On the Significance of Jaundice in

Diagnosis, by Dr. Wm. E. Quine. The Effect of Noises Upon Certain Forms of Deafness, Dr. G. F. Hawley. A Case of Genito-Urinary Surgery and Median Lithotomy, Dr. Wm. L. Axford. Pathological Specimen of Papillomatous Ovarian Cystic Tumors, Dr. Charles T. Parkes.

The first paper, on the "Significance of Jaundice in Diagnosis," by Dr. Wm. E. Quine, of which the following is a brief synopsis:

After alluding to jaundice of obstructive and non-obstructive origin, and to the various theories that have been advanced in explanation of the latter, the writer succinctly pointed out that the attendant symptoms were mostly due to the presence of colorless bile acids, the bile pigment being harmless. Cerebral disturbance due to hepatic derangement, and associated with cholæmia, was not caused by the presence of normal bile, but by a different though unexplained species of toxæmia, although slight jaundice is often overlooked, and in some instances cannot be distinguished from cachexiæ, except by the discovery of bile acids in the urine. The diagnosis usually relates to the discovery of the cause, and not to the mere recognition of the effect.

1. Jaundice occurring suddenly, in apparent health, and painlessly, is usually of emotional origin, and transitory.

2. When it depends on disease or injury of the brain, acute atrophy of the liver, snake poison, or an infectious fever, it is always associated with mental disturbance.

3. If it be attended with fever, and well marked, it is secondary to inflammation of biliary passages, pneumonia, toxæmia, or infective inflammation of the portal vein.

4. If it occur suddenly, and is preceded by paroxysmal pain and vomiting, it is caused, nine times out of ten, by biliary calculi.

5. If it be preceded by typical symptoms of gastro-duodenal inflammation, it is obviously of catarrhal origin.

6. Impassable obstruction of the common duct is shown by great intensity of jaundice, clay-colored stools, and in recent cases by distension of the gall-bladder.

7. Jaundice caused by sudden obstruction of the biliary passages is always associated with paroxysmal pain and nausea, but there is no means of ascertaining the nature of the obstructing body, except its discovery in the stools.

8. In the rare cases of sudden obstruction by cancerous, hydatid and aneurismal tumors, there is almost always a history of impaired health, enlargement and deformity of the liver, ascites, etc., which, aided by the revelations of physical exploration, will lead to correct differentiation.

9. Sudden return of normal coloring to fæces confirms the diagnosis of obstruction.

10. Occlusion of the cystic duct may be attended with as much pain, nausea, and distension of the gall-bladder, as occlusion of the common duct, but there is no jaundice. In occlusion of the hepatic duct, the same symptoms are present, including jaundice, and excluding distension of the gall-bladder. It is often

impossible to distinguish between occlusion of the hepatic and the common duct. The former is rare because the duct increases in size from above downward.

11. If jaundice persist after the symptoms of biliary colic or catarrhal inflammation have a month since disappeared; or if jaundice have disappeared after a biliary colic, to return slowly and painlessly, it may be assumed that stricture of the duct has resulted from inflammatory thickening, adhesion of walls, or cicatrization of an ulcer.

12. A history of repeated attacks points to the probability of gall stones.

13. If jaundice come on slowly, without antecedent colic, or catarrh, and without attendant evidence of impaired health or portal obstruction, it is probably caused either by pressure upon the duct, or by the growth of a tumor within its walls. The pressing body, when large enough, may be readily appreciated, as in the case of pregnancy, ovarian tumor, aneurism, distended colon, etc., but when it is small, or constituted by enlargement of lymphatics in the fissure of the liver, it is apt to escape detection.

14. Slight but persistent jaundice may be due to incomplete occlusion of the common duct, or to complete occlusion of a branch of the hepatic; but usually it is found associated with either valvular disease of the heart, some disease of the lungs which obstructs circulation, or cirrhosis of the liver.

15. If ascites be associated with it, the disease is either cirrhosis or cancer of the liver. If the liver be abnormally small, the disease is cirrhosis; if it be large, the disease is either hypertrophic cirrhosis or cancer. Differentiation between the two is seldom attended with difficulty.

16. Absence of jaundice does not imply absence of hepatic disease, since the liver may be destroyed by disease, or extirpated by operation, without jaundice ensuing.

17. It is not a prominent symptom of hepatitis if catarrhal inflammation of biliary passages be rigidly excluded. It is not characteristic of hepatic abscess, where, at most, mere muddiness of the complexion is usually seen. These affections are rare in temperate climates, and when encountered, are generally found to be secondary to direct injury of the liver, or to infective inflammation of the portal vein. It is not a symptom of waxy or fatty liver, or of hydatids, excepting as an extraordinary complication.

DISCUSSION.

Dr. G. C. Paoli said, there is no doubt but in many serious derangements of the liver, few or no symptoms of jaundice are present. If so, they are passed unnoticed. In a clinical point of view, the paper is a most valuable one, and others should be written and cases presented. In scirrhus of the liver, oftentimes, there may be no pain and but light pigment deposit, in advanced stages of the disease. In other maladies, too, there will probably be but very little icterus, and no bilious excretions passed from the bowels. In a chronic state of the liver, where there is no organic trouble, we may pass by the yellow appearance of a conjunctiva, as, being a symptom of liver diffi-

culty, and during the early stages of cirrhosis or cancer of this organ, we will probably not diagnose it.

Dr. S. H. Stevenson asked the writer to explain more particularly regarding cholesterine, and obstruction of the gall duct, if these conditions are toxic in effect, or if they produce cerebral disturbances.

Dr. J. J. M. Angear, who argued at some length, stated, that if the odor and clay-colored stools came from the large intestine, and this had nothing whatever to do with the bile or small intestine, then he could not understand why the liver excreted bile. To give mercury produces dark-colored, offensive stools, because why? it affects the large intestine and liver. Physiology tells us bile destroys the red corpuscles of the blood. If the coloring matter of bile, then, is nothing more than the coloring matter of the blood, then why not take the position, that, inasmuch, if bile be toxic, that some poison has entered the blood, and that the icteric condition of a conjunctiva and mucous membranes has nothing to do with the liver? why not, I say again, take the hypothesis that there has already existed a blood-poisoning? and closed by complimenting the writer on the many good points contained in his paper.

Dr. J. H. Etheridge inquired, if people at times who are laboring under mental emotion do not become greatly jaundiced? Is it not a fact that pigmentary substances contain more than one kind of coloring matter? Regarding those who are hurt or injured, when they become jaundiced, is it due to a vascular condition, or to reaction? or is the icterus due to a nervous condition or to shock of the nervous system, or to a change resulting from a condition of the vascular merging into a nervous system?

Dr. C. T. Fenn stated, in cases of hepatitis, that result fatally, a condition just after death resembling icterus will come on, due to the cause of death, namely, abscess of the liver. If this be so, he queried the reason of it?

Dr. R. Tilley and others debated the subject, and Dr. Quine closed, but would not attempt to answer all the questions, nor could he inform the members where to seek for the necessary information. But it has not been proven that bile is toxic, nor that cerebral disturbances result from it. The blood and secretions may be saturated for years, and no cerebral disturbance follow. And in cases of obstruction of the common duct, no phenomena of cerebral disturbance need develop. Regarding the secretory functions of the liver and feculent discharges, the theory advanced by one speaker is not sustained by the every day practitioner, although some remedies do increase the secretory action of the liver. Regarding jaundice not appearing in scirrhus, he thought this was erroneous. The paper did not dwell upon the conditions that are present in catarrhal jaundice, biliary calculi, nor congestion of the liver. The condition of insanity or emotional mental trouble is differentiated by the history of the case. Regarding Dr. Fenn's interrogatory, he did not know that jaundice occurred after death.

"The Effect of Noises upon Certain Forms of Deafness," by Dr. G. F. Hawley.

More than two hundred years ago Dr. Thos. Willis, of Amsterdam, described certain forms of deafness in which hearing was improved by noise, enabling persons to distinguish tones and sentences which at other times would be unheard. This symptom, bearing the name of Paracussio Willisiana, has been accepted by most aurists, but no satisfactory explanation as to its cause has been advanced.

While Politzer, Von Trolsch, and others, consider that it depends upon some change in the position of the ossicles or membrana tympani, many like Kramer take different views, and believe that it is due to a stimulating of the auditory nerve, thus forcing it to a more healthy action. Experience favors the theory that the middle ear is the seat of this symptom, that some change is brought about by the constant noise which restores the hearing for the time being.

What this change is, is still open to discussion. It may be of interest to relate the following case which came under the writer's observation while house-surgeon at the Golden Square Hospital, London. Mrs. H., aged 30, had for the last five years suffered with marked deafness in both ears. Common conversation was heard with difficulty except when any loud noise was present. At that time the hearing apparently was greatly improved. A watch could be heard on the left side only upon contact, and on the right at a distance of about two inches. The tuning fork showed no trouble of the acoustic nerve, but clearly indicated some disturbance of the middle ear. The drum-head was normal as to tension, color, etc. While perfect movability existed in the malleo-incudal joint. Nothing indicated ankylosis of any of the ossicles. The appearance of the throat was healthy and the eustachian tubes both patent. This is a good example of this form of deafness in which the symptom of hearing better in a noise manifests itself. Roosa, however, mentions two cases where the drum-head was more or less destroyed and still noises improved the hearing. The ossicles in both cases were intact. Politzer, in his work on Aural Surgery, states that this improvement is seen only in middle ear affections of an adhesive or sclerotic character, and regards it as a most unfavorable symptom for satisfactory prognosis. Roosa, on the contrary, states that it is found in many forms of ear affections, and does not necessarily forbid one from expecting favorable results from treatment. In his article on "The effects of noise upon diseased and healthy ears," he says, I have known two cases where this symptom occurred in patients who regained their hearing perfectly. While the symptom frequently accompanies incurable diseases of the middle ear, I believe it is a very frequent symptom in sub-acute cases where both ears are affected. Of course it would not be observed in disease of one ear only. Whatever may be the cause of this symptom, we are justified, the writer thinks, in believing that certain pathological changes are then present in the middle ear which will be found at no other time. If this be true, in what does the change exist? Willis considered the change brought about by the action of strong wave tone upon a relaxed membrana tympani to be the cause of this symptom. As long as

the drum-head is in a relaxed condition it refuses to respond fully to wave impressions. It is no longer a perfect sound-conductor until its tension is restored. Noises by forcing air against the membrane press it inward, restore its tension, and hearing is improved until the pressure is removed, when deafness returns as bad as ever.

If this improvement were found only in such cases as he describes, we might accept his theory as correct, but unfortunately, as already stated by the writer of the paper, it is present with no change whatsoever in the drum-head. Therefore, in such cases at least, this improvement in hearing is due to some other cause. We have in the middle ear two other elastic membranes, one of which takes as important a part in conveying wave impressions as the membrana tympani. Any change by disease or injury would be fully as disastrous to normal hearing, *i. e.*: By this the writer means the membrane of the foramen ovale. When we consider the extraordinary fine shades of vibrations transmitted by this membrane to the fluids of the labyrinth, are we not justified in expecting that any loss of accuracy and precision on the part of the transmitting apparatus at this point will cause a corresponding loss of hearing power? According to Riemann the excursions of the stapes in the fainter tones are so small as to escape detection even with the highest power of the microscope. Therefore a corresponding sensitiveness on the part of the membrane must necessarily be present in order to appreciate and transmit these vibrations. Thus we see that any change in the membrana ovale which tends to hinder the passage of the vibrations to the fluids in the inner ear must cause diminution in hearing. If then the membrane from any cause becomes relaxed, and loses the power of responding to vibrations, it acts no longer as a sound conductor, but as a damper to any wave impressions. This is demonstrated in the case of relaxed drum-heads where inflation improves the hearing. Not only must this elastic plate (so-called by Politzer) be capable of responding fully to any wave impulse, but it must also bear a certain relation to the foot of the stapes, *i. e.*, a due amount of pressure must be applied by the stirrup and a sufficient resistance be afforded in every ear that possesses perfect hearing. If this is lost, deafness is the result. Chronic suppurative inflammation of the middle ear with destruction of drum-head, incus and malleus is a proof of the correctness of this statement. Hearing is here frequently improved by a false drum-head, which presses the loose stapes against the membrane of the foramen ovale, thereby restoring the relative positions of the parts. In a relaxed membrane the pressure of the stapes is wanting, due to an absence of resistance in the diseased membrane itself. Until we find some means of restoring this needed resistance, deafness remains. Thus, through the loss of elasticity in this membrane, we lose two important factors for perfect hearing. First, this membrane, like the membrana tympani, while relaxed refuses to act as a conductor of sound by not responding to vibrations given it; and, second, the proper relation between it and the stapes is destroyed, the necessary pressure and resistance being absent. We find in the

case of an atrophied drum-head that hearing is frequently improved by inflating the middle ear, which restores the tension of this membrane by forcing it outward. One might suppose that such inflation would likewise restore lost hearing if due to a relaxed membrane at the oval window. Unfortunately the act which might restore to this membrane its proper tension, forces it inwards as well, and thus separates the stapes from it. Though the membrane may be in a proper condition for receiving and transmitting wave sounds, the stapes from the absence of any pressure applied by it to this membrane will be unable to perform its duty, there will be more or less obstruction to the passage of sound at this point. Whatever then restores the hearing in these cases must not only renew the tension of the membrane but maintain as well the relative position of health between it and the stapes. This, in the writer's opinion, can only be accomplished by some influence brought to bear upon the membrane and stapes from outside the middle ear. If now we consider the effect of wave impulses upon the membranes and ossicles, we can understand how a loud and continuous noise (as the writer thought) might improve the hearing where the deafness is due to such pathological changes as herein described. The air, set in motion by this noise, strikes upon, and pushes the drum-head ossicles inwards. This crowds the air in the middle ear against the membrana ovale, which if relaxed is made tense by this pressure. At the same time the relative position between it and the stapes as to pressure, etc., is also restored, and hearing for the time is therefore improved. The noise which would confuse with normal hearing is absorbed, so to speak, in removing the cause of deafness. In case of perforated drum-head the vibrating air acts directly upon the diseased membrane and stapes.

Von Trolsch mentions a case where a magistrate so afflicted improved his hearing by pressing a bit of stick against the drum-head. Allen also, in his work on Aural Surgery, states, while speaking of this symptom, that the hearing power was increased in a patient who presented herself with marked distention of the drum-head, by pressing cotton against the ossicles. Another is also noted where large perforations existed. Here, before and after the healing of the perforation, hearing was improved by pressure.

Though these three cases do not in themselves place this theory beyond dispute, it may make it still worthy of further consideration.

It may encourage us to further investigations, which perchance may result in establishing beyond a doubt the cause of improved hearing in certain forms of deafness, by noise.

DISCUSSION.

Dr. S. J. Jones. This subject has been of much interest to pathologists, for different causes produce the condition alluded to in the paper, and it is not therefore always dependent on the same cause. A noise that may affect an abnormal ear will probably have no effect on the normal ear of a person. In some cases of relaxed condition of the stapes, the hearing power is increased by pressing cotton over

the region of it. A tuning fork placed between the teeth in a state of vibration, is also better heard in the affected ear of some persons. Also, in placing the hand on a piano in the transmission of delicate sounds, the affected ear is oft-times excited to action by the sound.

Dr. R. Tilley did not accept the adopted theory of the essayist, although some people can hear better during the presence of loud noise. If, as is a fact, when a relaxed condition of the mucous membrane of the middle ear exists, and we inflate it, the person can hear practically well for ordinary purposes with patent eustachian tubes.

MEDIAN LITHOTOMY. This operation was performed by Dr. Wm. L. Axford, who verbally cited the history of the following case of genito-urinary trouble. An old man, ætat 66, of inherited gouty diathesis, occupation gardener, had been during the last year and a half a sufferer from repeated attacks of nephralgia, which could only be relieved by hypodermics of morph. sulph. gr. $\frac{1}{4}$. After several attacks this remedy seemed to have no effect in affording him relief, neither did suppositories of belladonna and other anodynes appear to have any control of the pain. He was also a sufferer from chronic cystitis. Some time since the patient was again seized with the kidney trouble and cystic, combined, which continued three days, his urine was voided in small quantities very often, as frequently as every five minutes part of the time. The bladder was full continuously, and catheterization was resorted to every six hours. This produced excessive pain, which continued in spite of large doses of opium, for four hours after. Hyperæsthesia of the urethra became very marked, and this procedure of using the catheter had to be abandoned. It was also ascertained that he had an enlarged prostate. As a last resort the operation for median lithotomy was done, which very much relieved him, and thus he was saved the torture of many catheterizations. A drainage tube was inserted, this had to be frequently removed and freed from the deposits of phosphates and retention of mucus. The urine was excessively ammoniacal and fœtid. But the patient survived only a few days. Autopsy, cirrhotic gouty liver and kidneys, cystitis of aggravated and obstinate form, enlarged prostate, etc.

The speaker thought he was warranted in making the median incision in the case he reported, and should do so again under similar circumstances.

Dr. C. T. Parkes supported Dr. Axford in what he had done in the case of cystitis—that these cases were best relieved in the manner just stated. He then briefly alluded to two cases of a similar nature, relieved by this method, that remained so for six months. Dr. Parkes then gave an interesting verbal report of a case, and also exhibited the specimen, which consisted of papillomatous multilocular cysts of both ovaries. The cysts had ruptured, and discharged their contents into the peritoneal sac. The history of enlargement embraces a period of only six months. The patient stated she never had an illness previous to the commencement of the abdominal enlargement. She has emaciated rapidly and to great

extent. The patient measured 44 inches in circumference at height of umbilicus. The greatest difficulty in the case was the differentiation between ascites and ovarian cyst. There was no œdema, nor had there ever been, of the lower extremities. Percussion gave dullness in all directions—lying, standing, or sitting, the only place of resonance being in the epigastrium. Fluctuation was very distinct on the slightest touch in all directions. Pelvic examination ascertained that fluctuation was not to be felt in the pelvis. By this was also determined the presence of a small growth about the size of the closed fist on the right side. The uterus was displaced forward, close behind the pubes; cul de sac of Douglas filled with foreign body. *Diagnosis.*—Ovarian tumor; ruptured sac; contents emptying into peritoneal sac. *Operation.*—22 quarts, or 44 pints of fluid were evacuated from the abdomen and tumors; fluid of a dark amber color. No large amount of lymph was precipitated in it after standing. Both ovaries were found diseased, there being present in the left side a ruptured papillomatous tumor. It still contained some fluid, which could not be pressed out at the site of papillary growth. The right one had not ruptured, but was bound down deeply in the pelvis by adhesions. The pelvis was filled by these tumors and their adhesions. After much trouble the tumors were enucleated and removed, which were, at this point of the speaker's remarks, shown to the members. The operation was done recently, and during the first four days the temperature of the patient had not reached 100° F. She was strong and cheerful, and she was doing well in every respect, but was not yet out of danger. Bleeding was quite free immediately after the separation of the adhesions, but soon ceased altogether under pressure with dry sponges. A drainage-tube was left in the lower end of the incision down to the bottom of the pelvis, anticipating free discharge from such an extensive raw surface. The drain was very free through it for two days. The sigmoid flexure of the colon was adherent for two inches to one of the cysts. For the past few days the temperature was normal.

Dr. A. R. Jackson remarked: The distension by the fluids, in this case, prevented the intestines from rising to the highest point in the abdomen; and it required, he thought, great skill on the part of the operator to differentiate such a case from one of ascites, hydronephrosis, or ovarian tumor, although before proceeding to operate, an examination of the fluid would have determined it to be ovarian or otherwise. Drysdale has made 2,500 examinations, and, with but one or two exceptions (the speaker thinks), has succeeded in finding the characteristic pathognomonic cell in ovarian cystic fluid. L. H. M.

DOMESTIC CORRESPONDENCE.

EFFECTS OF ALCOHOL.*

TO THE EDITOR:

Your first question:—"How does it happen that during its presence (that of alcohol), not only the

products of combustion, but the sum total of all eliminations are diminished?" is premised upon a subtly devised sophism, and by the right of discovery I claim the opportunity thus afforded me—and with such an antagonist I may not soon find another—of asking, what proof can you bring forward in support of the assertion evidently conveyed by the question? Neither in lecture nor communication, have I attempted to show that the temperature of the body could be raised or lowered by the exhibition of alcohol. True, you mention that Anstie noticed a lowering of the temperature, and as you are no doubt well aware, this was in cases where complete stupor, or a condition of anæsthesia had been reached. As having a special bearing on this point, the investigations of Drs. Parkes and Wollowicz certainly occupy a front rank. From these authorities we learn that a healthy young man was given, for a period of six days, a quantity of alcohol varying from one to eight ounces daily—in diffused quantities—and subsequently twelve ounces of brandy daily, for three days, thermometric observations being made every two hours in both cases, with no perceptible decrease of body heat beyond that observed during a like period of water drinking. In support of these authorities, I might cite the statement of Rickard, who on one occasion gave as much as twelve ounces of brandy to one individual, and in "straight" drinks, without being able to note the faintest lowering of temperature.

Speaking of "the lessening of the eliminations," I know that Böcker and Hammond are of opinion that alcohol and beer tend by their use to lessen the formation of sulphuric and phosphoric acids, urea and the extractives, while diminishing the water and acidity of the urine. But, opposed to this, we find Parkes and Wollowicz declaring that neither alcohol, brandy, nor claret produce any decrease in the elimination by the urine of urea, phosphoric acid, or free acidity. That the latter investigators have the weight of evidence on their side, at least as regards acid reaction, can be easily proven by any practitioner, at the expense of a few strips of litmus. Indeed, the writer can offer nearly a thousand insurance examinations, during 1880-81, made among a class of men who in moderation or otherwise were accustomed to the use of alcohol,—as proof that their indulgence did not materially lessen acidity of the urine. In the majority of these tests only litmus was used, but in many of them a quantitative as well as qualitative analysis was made.

Your partial admission that alcohol tends to bind up the albuminous material of the body in new combinations, sufficiently answers the question referring to M. Dupre's experiments. If by its affinity for certain tissues, alcohol seeks to protect those tissues from impending destruction, for so long a period as several weeks, and then leaves them unimpaired, and itself remains unaltered, as you would have your readers infer, we cannot but praise the spirit for its evident good behavior while in the system. When we consider that the most recent investigations teach us to regard the oxidation of albumen as the necessary prelude to the formation of fibrine, and the oxi-

dation of this constituent of the muscles and blood as leading to the production of colloidal material, the importance of even the catalytic or mechanical action of alcohol is at once made manifest. In short, if disease be regarded "not as a foreign entity, which takes up its residence in our tissues, producing disturbance and destruction, by a new and foreign material, but rather as a misdirection given to our normal functions, by agents other than 'minute organisms,'" it is certain that though alcohol may not claim a place in the healthy body, it can with propriety be given a place in the diseased one. "The eucalyptus tree makes sweeter the heavy air of the Campagna, and the maggot in the putrid mass but purifies it." In like manner may not the much abused, because so little understood, alcohol serve by its mere presence to tide the tissues over the point of impending destruction by the mechanical or molecular combinations you suggest.

The concluding hint that, if pushed to a logical result, my argument would place alcohol, opium and tobacco in the same category, might be answered by quoting the Duke of Argyle, who in a recent work, tells us that: "The world is the correlation, the fulfilment and the sanction of the instincts, capacities and longings of psychic existence." Indeed, the consciousness of a reserve power in man, argues future opportunity for its adequate exercise, and though man in satisfying this longing may reach the very limit of this reserve power, as regards his appetites, and transcending the limit of proper indulgence, trespass upon the domain of license or abuse, of alcohol, opium or tobacco, such abuse is no more argument against their legitimate use, than citing the gluttonous feasts of classic or medieval days, would be an argument against the modest spread of a Chicago physician.

Yours respectfully,

P. H. CRONIN, M.D.

*The above communication, the receipt of which immediately followed the publication in our issue of May 3, of a letter from Dr. Cronin and some queries addressed to that gentleman by the editor of this JOURNAL, has been unavoidably crowded out of our columns until now, by the unusual press of matter requiring space in the JOURNAL during and after the meeting of the Association.—ED.]

MISCELLANEOUS.

OFFICIAL NOTICE.

ANNUAL DUES from members of the Association—*Five Dollars* per annum—are payable directly to the Treasurer. Such payment entitles them to receive the JOURNAL of the Association for one year.

SUBSCRIPTIONS TO THE JOURNAL from those who are not members should be forwarded to the office of publication, Chicago.

BACK VOLUMES OF THE TRANSACTIONS may be procured, at reduced rates, by addressing the Treasurer.

THE INDEX to the 33 Volumes of Transactions will be forwarded, postpaid, on receipt of *One Dollar* by the Treasurer.

According to a resolution passed May 9, 1884, at the Washington meeting, continuous payment of Annual Dues is required, to retain permanent membership.

RICHARD J. DUNGLISON, M.D.,
Treasurer.

Lock Box 1274, Philadelphia, Pa.

GOOD LOCATION.—I have an established practice of twenty-five years, and will retire in the favor of the purchaser of my house, furniture, office, instruments, library, barn and team.

Care of this JOURNAL.

E. KNOWLTON.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT UNITED STATES ARMY, FROM JUNE 25, 1884, TO JULY 3, 1884.

Hartsuff, Albert, Major and Surgeon, (Fort Riley, Kansas,) granted leave of absence for one month with permission to apply for one month's extension, to take effect when his services can be spared. (Par. 6, S. O. 130, Headquarters Dept. of Mo., June 25, 1884.)

Middleton, J. V. D., Major and Surgeon, ordered to relieve Surg. B. E. Fryer from duty as Post Surgeon, Ft. Leavenworth, Kan., on or before July 1. (Par. 5, S. O. 133, Headquarters Dept. of Mo., June 25, 1884.)

Dickson, Jno. M., Captain and Assistant-Surgeon, assigned to duty as Post Surgeon, Alcatraz Island, Cal. (Par. 3, S. O. 71, Headquarters Dept. of Cal., June 19, 1884.)

Girard, A. C., Captain and Assistant-Surgeon, granted leave of absence for six months, with permission to go beyond sea. (Par. 11, S. O. 148, A. G. O., June 26, 1884.)

Girard, J. B., Capt. and Assis't-Surgeon, ordered to relieve Surg. W. E. Waters from duty as Post Surgeon, Plattsburg Bks., Plattsburg, N. Y. Surgeon Waters, upon being relieved, directed to return to his proper station, Madison Bks., N. Y. (Par. 3, S. O. 131, Headquarters Dept. of East, June 30, 1884.)

Benham, R. B., First Lieutenant and Assistant-Surgeon, from Dept. of Dakota to Dept. of Texas.

Gorgas, Wm. C., First Lieutenant and Assistant-Surgeon, from Dept. of Texas to Dept. of Dakota. (Par. 8, S. O. 150, A. G. O., June 28, 1884.)

Wales, Philip G., First Lieutenant and Assistant-Surgeon, from Old Fort Colville, Wash. Ter., to Fort Cœur d'Alene, Idaho. (Par. 3, S. O. 89, Headquarters Dept. of Columbia, June 23, 1884.)

LIST OF OFFICIAL CHANGES IN THE MEDICAL CORPS OF THE NAVY, FOR THE WEEK ENDING JULY 5, 1884.

Surgeon H. M. Wells, detached from Naval Hospital, Brooklyn, ordered to U. S. S. "Lancaster."

Dr. J. S. Sayre, Dr. F. J. B. Cordeiro, appointed Assistant-Surgeons. Commission dated 27 June, 1884.

OFFICERS OF
THE AMERICAN MEDICAL ASSOCIATION
 AND OF ITS SEVERAL SECTIONS, 1884-5.

PRESIDENT.

H. F. CAMPBELL, of Augusta, Georgia.

FIRST VICE-PRESIDENT.

IRREGULAR APOPLECTIC ATTACKS, DUE TO OTHER CAUSES THAN HÆMORRHAGE AND EMBOLISM.

BY GASPAR GRISWOLD, M.D., M.R.C.S.

Presented in the Section on Practice of Medicine and Materia Medica of
American Medical Association, May, 1884.

The term "*apoplectic attack*" is employed in the title of this paper to denote the sudden onset of a train of symptoms in which unconsciousness, hemiplegia and convulsions are more or less prominent. Many writers have used the word apoplexy to express a certain form of hæmorrhage, as in the terms *renal apoplexy* and *pulmonary apoplexy*; in this paper it will not be used in that sense, but will always be taken to mean the symptoms described, without reference to their causation.

The investigations of modern pathologists have clearly established the relation of apoplexy to the various forms of cerebral hæmorrhage, embolism and thrombosis, and have enabled us to distinguish between those conditions with considerable accuracy. We now understand that unconsciousness is usually most profound in cerebral hæmorrhage; that consciousness may be preserved in embolism, even where hemiplegia is well-marked; and that in meningeal hæmorrhages unconsciousness and convulsions may occur, and yet hemiplegia be ill-defined. These differences, and many other important facts, have been abundantly verified by *post-mortem* examinations, and the diagnosis of organic brain disease has in the last few years been put upon a very satisfactory basis. When, however, we come to study the symptoms which are produced where the circulation of the brain has been disturbed by functional causes, instead of by organic lesions, we are at once met by difficulties. Hæmorrhage, thrombosis or embolism is easily determined by *post-mortem* examination, but it is often impossible at an autopsy to decide whether the brain was anæmic or hyperæmic just before death. Moreover, cases of functional disturbance of the cerebral circulation, even when sufficiently severe to cause the most alarming symptoms, rarely terminate fatally. *Post-mortem* examinations, then,

which have done so much to clear up everything connected with organic brain disease, can assist us very little in studying those affections which depend merely upon functional irregularities in the cerebral blood supply. Whatever information we have on this subject is mainly the result of experiments and of clinical observations, and may be summarized as follows: 1st. Sudden *anæmia* of the brain causes unconsciousness and convulsions. This anæmia may be produced by failure of the heart's action, by pressure upon the carotids, or by the action of the vaso-motor nerves. The vaso-motor nerves may act in two ways to cause anæmia of the brain: first, *directly*, by causing contraction of the cerebral arteries; second, *indirectly*, by causing dilatation of the abdominal blood-vessels, thus lowering the general blood-pressure and draining the blood from the brain into the vessels of the trunk. 2d. *Venous hyperæmia* of the brain, through the privation of oxygen which it involves, has the same effects as anæmia. 3d. *Arterial hyperæmia* of the brain is more difficult to produce artificially than the preceding conditions, and has been less carefully studied; modern pathologists are inclined to look upon it as a rare and comparatively unimportant event. This is in marked contrast with the views of our ancestors, with whom *active cerebral congestion* and *congestive apoplexy* were much talked of; modern observation, however, has proved that convulsions, dizziness and similar symptoms, which were formerly attributed to a rush of blood to the head, are in reality much more frequently dependent upon cerebral anæmia. This short summary of what physiologists and clinical observers have been able to teach us about the effects produced by variations in the cerebral blood supply is sufficient to show us in how many ways apparently remote influences can cause anæmia or hyperæmia of the brain, and how difficult it is to formulate the symptoms which may follow. The best understood of all the diseases depending upon disturbance of the brain circulation, and the one which has been most thoroughly studied, is epilepsy. A typical epileptic seizure is ushered in by contraction of the cerebral arterioles, the face becoming pale and the pupils dilating; unconsciousness follows, the patient falling to the ground in convulsions which are at first tonic, and then clonic. The convulsions last one or two minutes, and are succeeded by a condition of lethargy or semi-coma, which usually terminates in from ten to forty minutes; the patient then returns to his normal condition until the occurrence of the next paroxysm. Such a picture is not hard to recognize, and a diagnosis is usu-

ally easy. But suppose, from the same causes, we have an attack in which the ushering-in convulsions are so indistinct as to escape notice—nothing but a rolling up of the eyes or a few twitches. Suppose the unconsciousness lasts for hours, and is so profound as to merit the name of true coma—the patient cannot be roused, his pupils are dilated and do not respond to light, his breathing is stertorous and his face is cyanosed. If to these symptoms we add the transient hemiplegia which is occasionally seen with epilepsy, the condition will imitate apoplexy from organic lesion almost too closely to admit of detection. Attacks of vertigo from stomach disorder are very common, and are not often mistaken for anything else; but occasionally cases are met with in which the same conditions are in some way aggravated, and instead of vertigo, we find profound stertorous coma. Such cases, at first sight, and even after careful examination, often present all the symptoms which usually indicate grave organic lesions, and a correct diagnosis is rarely made until the sudden recovery of the patient points the way to it. And so in many ways, and under a variety of circumstances, apoplectic attacks may occur, so severe as to seemingly warrant the gravest prognosis, and yet terminating in recovery so suddenly as to make the existence of any organic lesion extremely improbable. It is well established that the symptoms which attend cerebral hæmorrhage, embolism and thrombosis, are mainly due to the disturbances of the intracranial circulation which they produce—in the case of hæmorrhage, by pressure of the clot on the surrounding tissue; in the case of embolism and thrombosis, by occlusion of the vessels of supply. Since disturbance of circulation is the essential factor in the process, it is not strange that similar symptoms should be produced, whether the blood current be obstructed by an embolus or by contraction of vessels—whether anæmia be caused by the pressure of a clot or by failure of the heart. A marked difference between the two conditions presents itself, however, when the persistence of organic lesions is compared with the rapid disappearance of functional irregularities. This subject may be most appropriately discussed in connection with the following illustrative cases, all of which were seen by other physicians, either accidentally at the time of the attack, or in consultation with the author. In all of these cases, an erroneous diagnosis was made at first by the author, or by a physician who was called in before him.

CASE NO. I.—*Apoplectic attack from cerebral anæmia following exhaustion and overwork.*

T. B., a young gentleman 24 years of age, finely developed, and who had always enjoyed excellent health, became exhausted from overwork during the hot weather in August, and passed some sleepless nights worrying about business. Returning home one evening much fatigued, he suddenly fell back unconscious. A servant, who is more than usually intelligent, was in the room at the time and observed no convulsive movements. All efforts to rouse the patient being of no avail, the author was sent for,

and found the patient profoundly comatose, making no sign when pinched or when ammonia was held to his nose. The breathing was stertorous, and the face cyanosed. The pupils were dilated, but not unequal. There was no evidence of any paralysis. The urine, drawn with a catheter, was in all respects normal. After the coma had lasted two hours, the patient recovered consciousness gradually and without nausea. His mental condition from this time on until his recovery—a period of five days—was very peculiar. It resembled very closely the delirium of fever. He would hold conversations with imaginary people, mistook his attendants for his sister or mother, and raved about his affairs, believing himself to be at his office. During all this time his temperature and pulse were invariably normal. He could walk feebly with assistance and gave no evidence of paralysis or any tendency to rotatory movements. Sensation was normal. The tongue when protruded did not deviate, and there was no aphasia. Examination of the retina and ear revealed nothing abnormal. The heart and lungs seemed healthy. The case was seen in consultation by Dr. George L. Peabody, and was very thoroughly examined. On the morning of the sixth the patient awoke with his mind perfectly clear; he presented no further symptoms and at once regained his health. He has remained well during the two years which have elapsed since that time. The author's first diagnosis was a probable slight hæmorrhage into one of the posterior lobes, basing this opinion upon the presence of coma followed by obscured intelligence, without any effect on motion or sensation. He now believes that the apoplectic attack was due to sudden anæmia of the brain, and that the subsequent mental impairment was due to the same cause in a less degree, and analogous to the delirium of inanition or starvation.

CASE NO. II.—*Apoplectic Attack Apparently Due to Retrocedent Gout.*—Mrs. S., a lady 60 years of age, and for fifteen years a sufferer from gout in the toes and fingers. She usually has four or five attacks in a year, and is always able to predict their coming by the appearance of prodromal dyspeptic symptoms, and marked diminution in the quantity of urine. In November last, while experiencing the usual prodromata and expecting an attack of gout at any moment, she suddenly became unconscious, falling to the floor. The nearest doctor was sent for at once, and on hearing the history and finding a gouty old lady comatose and hemiplegic, without hesitation gave an unqualified diagnosis of cerebral hæmorrhage, with a corresponding prognosis. The author saw the patient some hours afterward, when she had regained consciousness. She was still hemiplegic, the face, however, remaining unaffected. There was no anæsthesia. The tongue did not deviate, and there was no aphasia.

The lungs, heart and kidneys seemed normal. At the end of twenty-four hours her symptoms had all disappeared, and she experienced that relief from dyspepsia and scanty urine which was usual after gouty paroxysms affecting the joints. Since then she has had one attack of gout in her toe, but in all

other respects has been well. This case is analogous to those described by Garrod, in which coma or hemiplegia occurs after prodromal gouty symptoms, and seems to take the place of the joint manifestations. Gouty deposits of urate of soda have never been found in the brain or its membranes, hence these attacks do not seem to be, strictly speaking, a transfer of the morbid process from the joints to the brain. They probably depend upon some disturbance of the intra-cranial circulation, which is sufficient to cause symptoms, and yet does not involve the production of tophaceous deposits.

CASE NO. III.—*Apoplectic Attack from Stomach Disorder*.—Mr. W., a gentleman 56 years of age, habitually enjoys good health, but is apt to occasionally overwork himself. He returned home one afternoon very much fatigued, and went to his room to dress. The servant who came to announce that dinner was served received no answer, and on looking into his room saw him in an arm-chair, apparently asleep. On advancing to wake him she noticed that he was breathing heavily, and presently saw that his clothes were covered with matters which he had vomited. Two doctors were called at once, who found him profoundly comatose, with stertor and cyanosis; they made a diagnosis of cerebral hæmorrhage, with a grave prognosis based upon the very deep coma. After another hour the patient began to regain consciousness, and although he remained for awhile somewhat dazed, yet at the end of four or five hours from the time of his first seizure he was fairly himself again, and spent a good night. The next morning he arose and dressed himself as usual, and has been well ever since; it is now three years since the attack. In this case we have sudden unconsciousness, along with the vomiting of a large quantity of undigested food, which had been eaten at least five hours before, and should have been absorbed by that time if the stomach had been normally active. Profound coma was present for two hours, followed by three hours of mental confusion. At no time was there any appearance of paralysis; and as no one saw the commencement of the attack, it is impossible to say if any convulsions occurred at that time. Examination of the heart, lungs, and kidneys, gave only negative results. This seems to be an instance where stomach disorder produced symptoms of which vertigo is simply a lighter shade, differing only in degree. No hæmorrhage ever produced more profound coma than was present here for two hours, and yet the patient was well the next day and able to attend to business.

CASE NO. IV.—*Apoplectic Attack—Cause unknown*.—Mr. E., a merchant, 28 years of age, enjoys good health and is an active business man. One evening he was taking supper at a restaurant, having been to the theater. As he rose to put on his overcoat, he suddenly fell to the floor unconscious, no convulsive movements being observed by the friends who were with him. A physician was called at once, and finding him still comatose with his right side paralyzed, pronounced the case to be one of cerebral hæmorrhage or embolism. The author saw the patient two

hours after the first attack; he had by this time partially regained consciousness, but was still hemiplegic, the face, however, being unaffected. Sensation was normal, or nearly so. There had been no vomiting. The tongue did not deviate when protruded, and there was no aphasia. Physical examination disclosed no disease of the heart, lungs or kidneys. The patient passed a quiet night, and when he awoke all the symptoms had disappeared. This occurred several months ago, and he has been perfectly well ever since. In this case we have sudden unconsciousness with hemiplegia, and the resemblance to cerebral hæmorrhage or embolism is at first altogether deceptive. We have here a fair type of what used to be called congestive apoplexy. Trousseau describes a number of such cases and believes them to be essentially epileptic. They differ from ordinary epilepsy in the slightness of the ushering-in convulsion, which is apt to escape the notice of friends and bystanders, and in being followed by deeper and more prolonged unconsciousness. When there is added the transient hemiplegia which occasionally occurs with epilepsy, it is almost impossible, as in the case just described, to distinguish the attack from one of cerebral hæmorrhage. The author saw a case two years ago which, during the first few hours, was the exact counterpart of the one just described. The age, the circumstances, the mode of onset, and the subsequent symptoms were identical even to the smallest detail. The author is confident that with those two patients before him to-day, side by side, he would be unable for four or five hours to determine in which an organic lesion was present. And yet one case recovered completely in twenty-four hours, and the other, though still living, is paralyzed to this day.

In conclusion, it may be stated that a positive diagnosis of organic lesion cannot with safety be made very early in any apoplectic attack, since the symptoms presented do not differ in kind or in degree from those which *may* be produced as a result of functional disturbance. The persistence of the symptoms seems to be the only reliable criterion. An exception to this statement may be made in favor of inequality of the pupils, which has never, to the author's knowledge, been observed with functional apoplectic attacks. The presence of this sign, associated with apoplectic symptoms and not dependent upon local eye trouble, may be taken as positive proof of the existence of organic lesion.

Dr. Janeway reported two cases of apoplectic attacks produced by excessive smoking. In these cases the attacks were not repeated after the patient gave up the habit of smoking.

Dr. A. Flint, Jr., referred to some of his experiments on animals, which went to show that cutting of the circulation of the brain was liable to produce convulsions. This he attributed to the anæmia of the brain rather than to the interference with the respiratory centres. He thought that the profession was coming to pay more attention to the effects of variations of the intra-cranial circulation than it had previously done.

THE NEW OFFICINAL CHLORATE.

BY TRAILL GREEN, M.D., EASTON, PA.

Read in the Section on Practice of Medicine and Materia Medica of
American Medical Association, May, 1884.

The introduction of the chlorates of the stronger alkaline metals makes an important era in therapeutics. The potassium salt was first used in medicine toward the close of the last century, but was not well known by the profession before the middle of the present century. Its properties and uses were well considered by our Chairman before this Section in 1882, and a paper was read by him on its uses in scrofula in 1880. All the journals have contained articles on this salt, and have given us various formulæ for its administration. It is safe to say that its properties and uses are now well understood. Every member of our profession can testify to its useful properties as a therapeutic agent, and all the younger practitioners must wonder how without this remedy we treated the various diseases in which we find it now to be so effectual, such as diseases of the mouth and throat.

The potassium salt was made officinal when the Pharmacopœia was revised in 1850, and the sodium salt in the revision of 1880. This addition to the Pharmacopœia of 1880 I shall show was a very important one.

Sodium chlorate was first described by M. Chenéviex, (Thompson's Chemistry of Inorganic Bodies, vol. II., p. 449). Having discovered its great solubility, I was led to the use of it in 1866, and I soon observed its excellent properties in the diseases in which the potassium salt had been used. In 1870, I called attention to it before the Medical Society of Pennsylvania. (Transactions of the Medical Society of Pennsylvania, 1870, p. 141). Since that time I think many practitioners have used the sodium salt, who had previously used the potassium chlorate, and they testify to its greater efficacy. I see cases constantly which prove its superiority. It is very well known that the potash salt is freely prescribed in almost every family *without the advice* of the family physician. I am called very frequently to prescribe for cases so treated which have remained ill for some time under suitable doses of the potash salt.

Under the use of the sodium chlorate I find such attacks yielding very soon. I observe the same result very often in office patients who have in like manner used the potassium chlorate. The superiority of the sodium salt is now so well understood in the families in which I prescribe, that they are in the habit of sending to me for it rather than to trust to that which they had been accustomed to use.

Having observed the good effects of the sodium chlorate in various inflammations of the mucous surfaces I was led to use it in cases of inflammation of the skin produced by rhus toxicodendron, and I found it very effectual, its early use arresting the inflammation very speedily, and when the inflammation had advanced before I was called to treat it I found that it allayed the itch-

ing and burning, and hastened the healing of the inflamed parts. In cases of this kind I have used four to twelve grams of the salt to 500 cubic centimetres of water (one to three drachms to a pint of water.) For about 18 years I have not used any other remedy for this annoying disease, and I see a great many cases of it, and I may say that I have received the testimony of physicians residing in different parts of the country to its pleasant effects in cases of this kind.

In the same article in the Pennsylvania Society's Transactions for 1870, I called the attention of the members to its usefulness in inflammations of the mouth and throat.

For the same period I have used this salt with great comfort to the patient, and with good therapeutic results in erysipelas, a solution of eight to twelve grams to a litre of cold water. I keep cloths wet with it constantly applied to the inflamed surface. I have not found any remedy so soothing in the itching and burning sensation so common in scarlatina—sponging the surface with a solution of the strength just named.

It is well to remember that in using the chlorates externally, we must be careful to keep cloths from the fire, which have been saturated with them, and have become dry, as such cloths are easily ignited, and burn with great activity. I have known cases of severe burns to occur in this way.

In conjunctivitis and inflammations of the eyelids, a solution of four grams to 500 c.c. of water I have used with great success. I have found it useful in all the inflammations which occur in the skin and in the mucous surfaces terminating in the skin, inflamed piles, inflammations of the external ear, the mouth and nostrils. I have not found any remedy so effectual in nasal catarrh, using a warm solution, four grams to 500 c.c. of water.

It is scarcely necessary to occupy the time of the section with extended remarks on all the different diseases in which I have found this salt beneficial. I may say that there are no cases in which the potassium salt has been found useful that will not be more rapidly cured by the sodium salt.

Its greater solubility than that of the potassium salt of itself commends this remedy; it being soluble in 1.1 parts of water, while the other salt requires 16.5 both at 15° C or 59° F. The advantage of this will be seen when in the case of children it is desirable to have the quantity of the solvent small, or when used as a lotion that we may have it of sufficient strength without having to use too much to accomplish the desired object. I think we fail in diseases of the mouth to effect cures with the other salt, because the strongest solution is not of sufficient strength to produce a local effect. This will relieve us also from all apprehension of crystals of the salt being formed in the kidneys. I know that some physicians have fear that this may occur when the other chlorate is used. I remember that on one occasion when speaking of its properties before a medical society, the question was asked by an intelligent physician in large practice, whether any injury was done to the kidneys from the use of this salt; from

which it appears some physicians do apprehend unpleasant effects from the potassium chlorate. I believe this fear is without foundation, but those who have it may be assured that no such trouble can result from the use of a salt so soluble as the sodium chlorate. After using it freely for many years, I can say that I have never observed any symptoms that indicated trouble in the kidneys from it.

Further, I believe it is well understood that sodium salts are more pleasantly received by the system than are those of potassium. I am well persuaded of this by all my reading on this subject from the time of my entrance upon professional life. Besides, the compounds of this metal, as shown by Verdeil,¹ exist in the blood in the proportion of 64.12 to 12.70 of potassium compounds, from which it might be supposed the compound most abundant in the blood would be received by the system with greater toleration. There is abundant evidence that this is true of the external application of the two substances in the form of their compounds. Of this we have had recent experience in the good effects of bi-carbonate of sodium in the treatment of burns. The corresponding salt of potash would hardly be prescribed as a suitable remedy in the treatment of a recent burn. I see from time to time that the profession is learning that sodium iodide and sodium bromide are better tolerated by the system than are the corresponding salts of potassium. The heart and the stomach are less disturbed by the compounds of one of these metals than by those of the other. I say the profession is coming to the belief that several of the potash salts are not so kindly received by the system as are the corresponding salts of soda. While preparing this paper during the last month I met with an interesting article by Dr. H. W. Berg, in the *Archives of Medicine* for the same month, on the substitution of iodide of sodium for potassium iodide, which is applicable to the subject of this paper. The potassium salts weaken the action of the heart. Bogolepoff, as quoted by Dr. Berg, has shown that sodium iodide produces no such effect on the action of the heart, and Boehm that the same is true as to the cardiac muscles or ganglia-muscular tissue cut from a living animal and placed in a solution of potassium chloride of the strength of two or three per cent. the muscular fibres immediately lose their irritability. If the muscle has not been immersed in the potassium chloride too long, immersion in a sodium chloride solution will restore the irritability of the muscular fibres. Kühne has shown that when healthy muscular tissue is placed in a solution of sodium chloride its irritability will be preserved for a much longer period than it is in a solution of pure water. Kühne has also shown that while potassium chloride has a paralyzing effect upon muscular and nerve tissue with which it comes in contact, sodium chloride restores and preserves the irritability of muscular and nerve tissue to which it is applied.

I refer also to Prof. H. C. Wood's *Treatise on Therapeutics*, 5th edit., p. 499. The most marked action of the potash salts is upon the heart. When

a frog is killed by a salt of potash, the heart is arrested in diastole, according to both Podocæpow and Guttman. The blood-current before death is greatly lessened in force, as was determined by Podocæpow by watching the circulation in the web, and by comparative experiment in regard to the rate at which blood flowed from wounded vessels in poisoned and unpoisoned frogs. In mammals, potash influences the heart even more markedly than in cold-blooded animals. Ten or fifteen grains of the chloride, quickly injected into the jugular vein, suffice to produce instant cardiac death. The action of a poisonous dose of potash upon the heart appears to be a local one.

By an elaborate series of experiments, Drs. Ringer and Murrell have shown that the potash salts in sufficient concentration act powerfully upon the cerebrum, the motor and sensuous nerves, and the muscles; in a word, that they are poisonous to all the higher forms of tissue.

Although the effects of large doses of compounds of potassium on the heart appear to be made out, definite knowledge is still wanting in regard to small doses. Traube asserts as the result of his experiments, that, injected into the blood in doses of two or three grains, the nitrate of potassium produces a fall in the pulse and a rise in the arterial pressure. Aubert and Dehn have experimented with a number of the salts of potash, and found, that with the exception of the permanganate, they all act upon the circulation in the manner just described.

Ringer and Murrell, applying the chlorides, iodides, and bromides of potassium and ammonium directly to the ends of the different nerves, found that they paralyzed, the effect of the potash salt being much the most harmful and permanent, that of ammonium the next, and that of sodium the least. When a potassium salt is given in large doses for a long time, it produces a condition of dyscrasia, with impoverishment and excessive fluidity of the blood.

Dr. Wood, *ibid.*, p. 509, says of the chlorate of potash: "Upon mucous membrane and ulcerated surfaces this salt acts as a powerful irritant, being, I think, even more active in this respect than the nitrate of potassium. Owing probably to its irritant influence, when taken internally in sufficient quantity it acts as a poison, although Dr. Tully is said by Stillé to have taken an ounce without injury. It is possible that, as with the nitrate of potassium, free dilution may affect the toxic properties. However this may be, it is certain that the chlorate of potassium has in a number of instances caused death. In Dr. Fountain's case an ounce of it produced almost immediately copious diuresis, followed after a time by persistent suppression of urine and marked symptoms of gastro-intestinal inflammation, with death on the seventh day. It is probable that in diphtheria deaths attributed to the disease have often really been produced by the chlorate. The minimum fatal dose is unknown, but a drachm given in the course of a night has killed an infant under a year old, and 3 drachms given during a day a child 3 or 4 years old." (*New York Medical Record*, 1878. Consult also *New York Medical Record*, 1879, I, 243; II, 454.)

¹Ann. der Chem. und Pharm., Band lxi, p. 89. Quoted by Dr. Carpenter. *Principles of Human Physiology*. Chap. IV.

Of sodium Dr. Wood writes, p. 610: "Unlike potassium, sodium and its salts have very little influence upon the higher animals."

Upon the blood the immediate influence of the soda salts is very slight, for Podocæpow asserts that one part dissolved in twelve parts of blood does not affect either the physical characters of the red corpuscles or the intensity of the ozone reaction.

Both Podocæpow and Guttman assert that even the largest doses do not sensibly affect the heart or the temperature; and the latter observer further declares that they are without influence upon the nerve-centers, the peripheral nerves, or the muscles.

The fact that soda in moderate amount has no depressing action, and indeed very little, if any, influence upon the general system, renders it preferable to potash in cases of acidity of the *primæ viæ*. It is, *par excellence*, the alkali for dyspepsia.

The knowledge of the physiological action of the compounds of sodium, prepares us to answer the question proposed sometimes by the families in which we prescribe concerning the preparations of sodium used in the culinary department. We certainly need not hesitate to say that, so used, we need not fear that the health of our clients will be affected. We learn from the study of the physiological action of potassium compounds, that the unprofessional use of chlorate of potassium, so common now among our people, must lead to the injury of the health. It is quite too common to find active remedies in the hands of those who know nothing of their properties, and still less of the nature of the diseases for which they use them. It will be well to exhort our friends to do themselves no harm by the use of those things of which they have no knowledge.

As therapeutists we certainly are so far ready to accept what is stated as to the effects of the potassium salts that we would not think it safe to use them in debilitated conditions of the system, and we assuredly can understand that their physiological action is such that their effect upon the muscular coats of the stomach, and the muscles of the heart, from long continued use must make such use unsafe in persons of more vigorous health.

From all that I have learned of the properties of the salt to which I have called the attention of the section, I feel assured that any one who will use it for a short time, will be so much gratified with its properties and action that he will never omit its use for that of the potassium salt.

ON SURGICAL TREATMENT OF GANGRENE OF THE LUNG.

BY DR. CH. FENGER, OF CHICAGO.

(Read before the Illinois State Medical Society in May, 1884.)

Since Mosler's drainage of a tuberculous cavity, pulmonary surgery has received considerable attention. Clinical observations have been made by Mos-

ler, Pepper, Koch, Bull, Hollister, and myself, and the subject has been studied in an experimental way by Gluck, Schmidt, and Bloch. In 1882, Bull, of Christiania, was able to tabulate 19 cases where operations had been performed for various kinds of pulmonary cavities. I shall limit my remarks here to cases of acute pulmonary gangrene. So little is known in this branch of surgery that it is safe only to draw conclusions from similar or identical cases. Acute gangrene of the lung, as is well known, is either diffuse or circumscribed. Diffuse pulmonary gangrene has never as yet and probably never will be interfered with surgically. Aside from its being, in all probability, an inevitably fatal disease, the course it runs is so acute, it is accompanied by such symptoms of depression and asthenic fever, that the condition the patient is found in will almost always exclude the thought of an operation. Circumscribed pulmonary gangrene, on the other hand, runs a more chronic course, its symptoms are less grave, and the patient, often for many weeks, retains sufficient strength to bear the strain and shock of an operation. In this respect surgical interference is justifiable. It has, indeed, been thought of and resorted to four times within the last five years by men in different countries, and more or less independent of each other, not having any accurate knowledge of each other's doings in this particular department of our science.

Let us briefly call to mind what is known about circumscribed pulmonary gangrene. It may be caused by an embolus, a bronchitis or a pneumonia; but no matter what its cause is, it presents itself in the beginning as a necrotic portion of lung tissue, varying in size from that of a bean to that of a hen's egg. This necrotic piece of tissue is sharply defined; after a while it is isolated from the living pulmonary tissue by a demarcating inflammation. It then lies in a cavity as a foreign body. It may be found there, according to Rokitansky, as a blackish-green, shaggy and moist plug bathed in ichorous fluid and of considerably smaller size than the cavity. It, however, happens still more frequently that the necrotic piece does not keep together in one mass, but is dissolved into a grayish-brown, very fetid ichorous pulp which is mixed with rotten, shaggy fragments of tissue; the walls of the surrounding cavity are lined by the same shaggy tissue infiltrated with ichor. The surrounding pulmonary substance is sometimes normal; more frequently it is in a state of inflammation, which has a stage of, or terminates in, hepatization. This hepatization may extend through the whole lobe affected with the gangrene. In cases in which the gangrenous cavity communicates with a bronchus, the bronchus affords a channel for the evacuation of shreds of necrotic lung tissue. The suppuration going on in the walls of the cavity may eliminate all the adherent shreds of dead pulmonary tissue, an abscess may form which, after evacuation of its contents, may close up, the (abscess) cavity may contract, and, finally, nothing is left but a scar to indicate the spot where there once existed a circumscribed pulmonary gangrene. Such spontaneous recoveries may take place, but how often they do so and under what circumstances, is altogether unknown. The usual course

of circumscribed pulmonary gangrene is quite different. A gangrenous focus from which the disease does not extend nor spread is rare. In many cases gangrenous destruction going on in its walls enlarges the cavity, and during this process the patient dies of exhaustion; in others, gangrenous matter is aspirated from the cavity up into the bronchial tubes, deposited in other parts of the lung, and a diffuse gangrene is produced. In a third class of cases the patients do not die during the course of the gangrene. The gangrenous cavity is emptied of its fetid contents, transformed into an abscess cavity, and the odor of the breath and sputa disappears, patient's appetite returns, he grows strong, and makes an apparent recovery. However, the abscess cavity does not close up nor contract; after months or years of more or less impaired health, the contents of the cavity undergo decomposition, the walls of the cavity are constantly being destroyed, and even a second gangrene may set in. The patients die of exhaustion, which, in the latter case, is accompanied by the usual symptoms of pulmonary gangrene. We know this much, that circumscribed pulmonary gangrene terminates in perfect recovery only when the gangrenous cavity is small. In the great majority of cases the disease ends in death. (Vide Herz in *Ziemen's Encyclopædia*.)

The prognosis of acute circumscribed gangrene of the lung is, of course, always grave. In any given case it is, during the whole course of the disease, impossible to foretell whether it will terminate in death or in recovery. A diffuse pulmonary gangrene, a gangrenous pyopneumothorax may supervene at any time, or the patient may die of exhaustion due either to the progressive local destruction, or to the accompanying fetid bronchitis. The internal remedies at our disposal at the present time can hardly be said to have any effect as far as regards checking the progress of the disease. They merely add aid in sustaining the patient, in keeping him alive till the gangrenous process has come to an end.

These facts, well considered, seem to justify the attempt to cure the disease by surgical measures; by them alone can we hope to put a stop to the progress of the local gangrenous destruction. Operations on the lungs with a view to bring about the healing up of gangrenous cavities have been performed in the four following cases.

CASES.

CASE 1. Messrs. Cayley and Lawson reported the following case at a meeting of the Clinical Society of London. (*Lancet*, No. 29, March, 1879, p. 440.)

A man, 45 years old, was admitted to the Middlesex Hospital, December 30, 1878. He had previously been laid up for five weeks with an acute pneumonia of the left lung. At the time that he entered the hospital he presented the usual symptoms of pulmonary gangrene with formation of a cavity in the lower lobe of the left lung. The general condition of the patient was not at all favorable for an operation. After an exploratory puncture had confirmed the diagnosis, Mr. Lawson made an incision in the ninth intercostal space just below the angulus

scapulæ. The cavity was evacuated, washed out and a drainage-tube inserted. Patient felt very much relieved, but four days after the operation he collapsed and died. Dr. Cayley pointed out that the only chances patient had of prolonging his life were those given by the operation, and that, if patient had come under treatment earlier, his prospects would have been better. At all events the operation gave patient some relief.

CASE 2. Gangrenous Cavity in Middle Lobe of Right Lung subsequent to Croupous Pneumonia.—Insufficient outlet through the bronchi—Adynamic condition of patient—Incision in the region of the angle of the scapula—Drainage with injections of carbolized water—Decided improvement for a week—Cessation of fetor of breath and expectoration—Return of fetid expectoration—Collapse and death twelve days after the operation. (Solomon Charles Smith, Halifax, England, 1879, *Lancet*, vol. ii., No. 3, 1880, p. 86.) The patient, a man about 60 years of age, had always been in good health, until two months previous to the operation, during which time he had had a little shortness of breath on going up hill. Two weeks previous to the operation he had a sudden attack of pneumonia of the right side, with chills, pain in the right side, pneumonic crepitus and rusty sputum. The case was not very severe, the temperature never exceeding 102°, and in about a week he got up. Two days later, the cough became worse, he felt weak, had to go to bed, and his breath had an offensive odor.

October 13, he suddenly expectorated half a pint of fetid gray fluid, and sank rapidly into a condition of collapse. On the next day, the patient was covered with clammy perspiration, his respiration was rapid and difficult, with loud tracheal râles; pulse 130, very feeble; could not lie down on account of the cough. The air of the whole room was extremely offensive on account of the gangrenous odor of breath and expectoration. The matter expectorated was principally a thick, tenacious, mucopurulent mass, but frequently alternating with this was a thin, gray, offensive fluid, which seemed to gush into his throat suddenly, in such quantity that he would spit out mouthful after mouthful of about half an ounce each, for three or four times in succession. The right side was slightly less resonant than the left, especially at the base, and at and under the right nipple. There was less respiratory sound on the right side and less vocal vibration, but all the sounds were greatly masked by tracheal râles; he had no pain; the tongue was brownish-black and dry, and the patient was very weak. Under invigorating and stimulating treatment he seemed to improve a little for a day or two, but then the expectoration diminished and he became worse. Four days later, a quantity of the same fetid fluid as before was expectorated, and he felt a little relieved, but soon afterward the expectoration stopped again and the adynamic condition of the patient increased.

On October 20, distinct cavernous respiration was heard below the spine of the right scapula, and external to and below the right nipple. The diagnosis was now made of a large cavity extending chiefly

through the middle lobe of the right lung, with no efficient outlet for the contained fetid matter, and a consequent adynamic condition of the patient from poisoning by the fetid pus. It was now resolved to operate, with a view toward procuring an outlet for the fetid matter, for the following reasons:

1. That the actual condition of the patient made it certain that he would die, and that very speedily.
2. That there would be some chance for his life if the cavity could be found and an opening made.
3. That it would be justifiable to explore with an aspirator, and if the cavity was found, to enlarge the opening and put in a drainage-tube.

At a point near the angle of the scapula, an aspirator-needle was inserted for three or four inches. No fluid escaped, but very fetid air was drawn through the tube. On holding a candle near the canula, the flame was blown to and fro during respiration, so that evidently a cavity had been reached.

Using the canula as a director, a knife was inserted between the ribs, and by the side of the knife dressing forceps were slipped in and the wound enlarged sufficiently to allow the introduction of a small india-rubber tube. Through the latter, a little carbolic acid solution was injected. This seemed to occasion a fit of coughing, when about half a pint of fetid pus, of the same character as the former offensive expectoration, was forcibly expectorated. The tube was left in the wound, which was covered by a large pad of a dozen folds of coarse muslin, wrung out of a solution of carbolic acid. This dressing was ordered to be changed every three hours.

For the first week after the operation, the improvement was very decided. For six days, the expectoration was very much diminished. The fetor also became much less, except at the time when the dressing was changed. He enjoyed his food more, and was altogether more comfortable. The respiration became much clearer in the left lung and the unaffected parts of the right lung, the moist sounds being much less frequent, and the tracheal râles only occasional. The discharge from the wound, however, continued extremely offensive, notwithstanding the daily irrigation of the cavity by a siphon. Whenever the dressing was changed, it was found to be soaked with a discharge for an area of five or six inches in diameter. As the water which escaped on washing out the cavity was only slightly stained, the offensiveness was attributed not to any retention of pus, but rather to sloughing within the lung.

Eight days after the operation the discharge had lessened a good deal, but the expectoration now increased and again became offensive. The pulse increased to 112; temperature, 100°. On the next day he was better, in the morning, had less cough and expectoration, and took food well. But the wound was beginning to slough, and a few gangrenous black shreds were discharged through the drainage-tube. In the afternoon he became very ill, with labored breathing, quick pulse, and profuse cold sweats. From this time he gradually became weaker, would take no more food, and died November 2, apparently from simple asthenia. An autopsy was not held.

CASE 3. A girl of 23 years was admitted to the

Hospital of Christiania, Dec. 13, 1880. E. Bull. (*Nord. Medic. Archive*, 1881, No. 17.) A month previous to her admission she had caught cold, began to cough and to expectorate yellowish muco-purulent sputa. One week afterwards her sputa, and, a little later still her breath, became fetid. Two weeks later she got a rigor, and at the same time she began to complain of pain in the left lung. The color of the sputa was now brownish red. She lost strength and had no appetite. At the time of her admission into the hospital her pulse was 104, temperature 102°, respiration 30. She coughed a great deal and expectorated a frothy fluid of fetid odor and tinged with blood. In the left axillary region the percussive note was dull, slightly tympanitic and large râles were heard.

On January 4 were discovered in addition the signs of a pleuritic effusion which extended over the posterior side of the left lower lobe. A few days later an exploratory puncture was made in the fifth left intercostal space, in the anterior axillary line. The syringe drew a bloody serous fluid which contained a great number of leucocytes.

January 19. Auscultation over the fourth intercostal space, near the anterior axillary line, gave the signs of a cavity. An exploratory puncture was here made with Pravaz's syringe, which drew a few drops of a bloody, purulent, fetid fluid. An exploratory puncture made below the left angulus scapulæ showed the effusion into the pleural cavity to consist of clear yellow serous fluid.

A gangrenous cavity was diagnosed, situated in the lower anterior part of the upper lobe of the left lung, and serous pleuritic effusion extending over the lower lobe of the left lung. The advisability of an operation was discussed.

On the 20th of December a swelling was found in the outer half of the left mamma, just where the exploratory puncture had been made into the gangrenous cavity. It was tender to the touch. The following day a subcutaneous emphysema was discovered on the anterior side of the left half of the thorax. A small incision made in the above described swelling gave exit to a little fetid reddish pus. On the 24th patient was anæsthetized, a transverse incision two inches in length, was made across the fourth intercostal space, and an abscess-cavity found below the mamma, containing a few tablespoonfuls of gangrenous pus, which was evacuated. In the fourth intercostal space an opening was effected with a pair of dressing forceps which were cautiously worked through the intercostal muscles and the adherent pleuræ. The index finger introduced through this opening, moved around in a cavity whose walls were composed of soft, friable, shaggy tissue. The cavity was washed out with carbolized water, a drainage tube inserted and an antiseptic dressing applied. After the operation her pulse was 128 and respiration 40. In the afternoon she coughed up a couple of tablespoonfuls of fresh blood. On January 25 she coughed less and felt better. On January 31, in the afternoon, she had several small hæmoptyses, and during the following days she expectorated matter considerably tinged with blood. Between the 3d and the 10th of

January the fetor of her breath would diminish one day and be worse the next. After the 10th of January her general health began to improve, the cough diminished, her appetite returned, and she felt stronger. After January 14, her breath and expectoration were free from odor; one week later the cough ceased entirely, as did also the fever. The wound healed, and the physical symptoms gradually became normal. After a long convalescence she recovered her full health. About six months after the operation she was able to resume her work as a servant girl.

CASE 4.—John Schubert, a German laborer, aged 39, had healthy parents, but does not know the later history of his brothers and sisters. Habits good. No venereal disease. Was healthy till nine years ago, when he had to keep his bed for a few days, and the symptoms of his sickness were fever. Made a perfect recovery. Five years ago he was taken sick with pneumonia, which he thinks was of the right lung, though he is not sure. He then was very sick for a few weeks, and recovered. As he became subsequently a member of a lodge, and was examined by their medical examiner, it is presumable that recovery had been entire. During this last winter he worked in a packing-house, and coughed more or less the rest of the winter.

February 29. After a week of aggravated cough, he had a chill which lasted a couple of hours, and took to his bed March 4. Dr. Valin was called to see him March 5. The respiratory murmur was absent from the lower third of right lung, and rather increased elsewhere.

Dullness was well marked over the same area, and pain was also complained of in that region, but there was some sensation of pain around the outer border of the diaphragm all around the chest.

There had been constipation for several days, to relieve which he was drinking an infusion of senna tea. The expectorations were mucous, and frequent. The respirations, 42 a minute, and distressing. The pulse 112, temperature 102. He was given whisky, 2½ grs. quin. every three hours, and Dover's powder liquid 5ss. every four hours.

March 6. There was some rusty sputa expectorated, which continued for a week, some streaks of blood being also present at times. Temperature during that time varied from 101 to 103, and was nearly normal. By March 15 the expectoration increased, and became more and more purulent. March 30 patient, upon very slight exertion, raised half an ounce of blood, and for the next three days some streaks of blood were present in the sputa, which from that time had a quite offensive odor.

April 5. Patient, upon trying to get up, had another hæmoptysis of about three ounces of blood.

April 6. Dr. C. Fenger saw the case in consultation, and found gangrene of right lung.

DR. H. D. VALIN.

April 6. I found patient lying in bed; pulse, 110; temperature, 101; respiration, 34. The air in the room, and especially in the neighborhood of the bed, had the fetid odor peculiar to gangrene. Patient's cheeks were a little flushed; otherwise he was pale,

looked suffering and somewhat collapsed. He was troubled with a distressing cough, which prevented him from sleeping during the night. In the twenty-four hours he raised more than a pint of expectorated matter, which, on being poured into a glass, showed the three layers characteristic of pulmonary gangrene—an upper frothy layer, a middle layer consisting of a grayish thin fluid, and a bottom layer consisting of yellowish muco-purulent matter, streaked with blood, and also showing streaks and flakes of a dark gray color. Stethoscopic examination revealed the left lung and the heart to be normal. Percussing the right half of the chest, a clear note was obtained in the supra-clavicular, the infra-clavicular, and in the mammary region as low as the upper border of the fourth rib. Below this the percussion note was dull. In the axillary region there was likewise resonance down to the fourth rib, and dullness below and in the infra-axillary region. Percussion on the back gave a clear sound in the supra and infra-spinous regions; in the infra-scapular region the note heard was not exactly dull, but less resonant than on the other side. On auscultation, normal vesicular respiration was heard in the supra and infra-clavicular and in the upper axillary regions. On the posterior surface of the lung, vesicular respiration was accompanied by large mucous râles. No distinct respiratory sounds could be detected in the area of dullness in the infra-axillary and infra-mammary regions. At a point one inch below the nipple, on the fifth rib, a "Ventillant," a sound produced by the opening and closing of a valve, could be distinctly heard. No other signs of the presence of a cavity were as yet perceptible.

The case presented no difficulties to the formation of a diagnosis of pulmonary gangrene in anterior part of the lower lobe of the right lung. It was furthermore evident that more palpable signs would soon develop of a cavity, which would be situated in a part of the lung accessible to surgical interference. I advised patient to go to the hospital, and, as his life might possibly be saved thereby, to have an operation performed as soon as the evidences of a well-marked cavity would appear to be sufficient to justify operative measures. He was admitted to the Cook County Hospital April 11, 1884. On account of the unbearable stench surrounding him, he had to be removed from the common ward and put in a separate room. In the meantime cough and expectoration remained unchanged; he grew weaker, had been delirious at times, and his appetite was entirely gone; his bowels were regular.

April 12. Morning, pulse 104; temperature 100.2°. Evening, pulse 112; temperature 101. The right lung was again examined, and the area of dullness found to be unchanged, stretching from the fourth rib downwards over the infra-mammary and axillary regions. But in the centre of this area there was now a smaller one in which the percussion note was tympanitic; it extended 1½ inches downwards from the right nipple, and 3 inches transversely from the axillary into the infra-mammary region. Auscultation of this tympanitic area revealed distinct amphoric respiration, and amphoric or metallic râles.

April 13. *Operation.*—At 11 o'clock in the morning, in the presence of Drs. Murphy, Baxter and Randall, of the attending staff of the Cook County Hospital; of Dr. Valin, patient's former medical attendant, of Dr. Verity, and of the house staff of the hospital, patient was anesthetized. A puncture was first made with a hypodermic needle in the mammary line, just below the fifth rib. From a depth of $1\frac{1}{2}$ –2 inches the syringe drew a thin, grayish-red fluid, which, on being poured into a glass, emitted the characteristic odor of gangrene. A transverse incision was now made, 3 inches long, parallel with the fifth rib, and having its mid point in the mammary line. The fifth rib was bared, and a $1\frac{1}{2}$ inch piece was resected subperiosteally. A hypodermic needle detached from its syringe, was thrust in through the costal pleura; on being let go, it was observed to make slight movements corresponding to the respiratory movements, but they were not of sufficient extent to disprove the existence of adhesions between the two layers of the pleura. A long hypodermic needle was then screwed on the syringe, and was thrust in in different directions until the syringe again filled with gangrenous fluid. The syringe was unscrewed from the needle while the latter remained in place, in order to be used as a guide leading into the cavity. A large funnel-shaped canal was made with Paquelin's cautery, which was gradually pushed along the needle through the pleura and the subjacent pulmonary tissue, till, at a depth of about $1\frac{1}{2}$ inch below the pleura, the cavity was entered. The opening was sufficiently enlarged to permit the index finger to enter the cavity, whose dimensions were found to be on palpation $3\frac{1}{2}$ inches transversely, $2\frac{1}{2}$ inches from above downwards, and about one inch antero-posteriorly. The walls of the cavity were felt to be rather firm and indurated. No shaginess nor detached shreds of pulmonary tissue could be detected. Drs. Baxter and Valin, who also made a digital exploration, confirmed these statements. The cavity was then washed out with a saturated solution of salicylic acid; as soon as it had filled, a vehement cough expelled the fluid mixed with air. Two large fenestrated drainage-tubes, and one of smaller size which was not fenestrated, were introduced into the cavity and held in place by a stitch to the skin. The whole operation was performed, so to speak, bloodless, as boring the pulmonary tissue with the cautery produced no hæmorrhage. The incision wound was left open, was dusted over with iodoform, and a heavy antiseptic dressing applied. Patient was brought to bed, and warming bottles were placed along his extremities.

At 1:30 P. M., the day of the operation, patient rested quietly; his cough had become less frequent. At 3 P. M. he asked for something to drink, and was given a glass of milk. Champagne, egg, lemonade, and milk with seltzer were ordered to be given when required. At 7:30 P. M. pulse 84, temperature 101.2° . Patient felt comfortable; he had some soreness and pain in the neighborhood of the wound. He was given a hypodermic injection of morphia and atropia and some cough medicine.

The air in the room was not exactly offensive.

The fetor of the expired air had diminished so much that I could now sit by the patient and speak to him without covering his face with a towel, as I had always been obliged to do before.

April 14. Patient had passed a comfortable night; pulse in the morning 96; temperature 100.4 . In the evening, pulse 96; temperature 101.2 . His cough had gone on diminishing. The expired air and the sputum still emitted a gangrenous odor; the quantity of the expectorated matter was about $\frac{1}{2}$ a pint. The dressings were saturated with a bloody fluid smelling of gangrene. The cavity was washed out with a solution of salicylic acid; this brought on a violent coughing, which caused several shreds of lung tissue, one of them $1\frac{1}{2}$ inch in length, to be thrown out at the wound through and beside the drainage-tubes. Toward the end of the coughing-spell, the fluid ejected from the cavity was tinged with blood. The walls of the canal I had made with the cautery through the pulmonary tissue were covered with a grayish-brown eschar.

April 15. Morning, pulse 92; temperature 100° . Patient had passed a comfortable night, although he had not received any morphia. Evening, pulse 92; temperature 101.2 . Patient was dressed; odor less marked; further shreds of lung tissue were thrown out.

April 16. Morning, pulse 90; temperature 100 . Evening, pulse 94; temperature 100.5° . Patient was dressed. There was less discharge and less odor; a few fragments of pulmonary tissue were thrown out.

April 17. Morning, pulse 84; temperature 99.6° . Evening, pulse 90; temperature 99.8 . Patient commenced to eat solid food.

April 18. Morning, pulse 85; temperature 99.0° . Evening, pulse 84; temperature 100.2° .

April 18. The wound had so far been dressed every day. The cavity was washed out but slightly on account of the distressing cough which invariably followed. There was now scarcely any odor to the breath or the sputa, which had diminished considerably in quantity. The whole (external) wound was now covered with granulations. The walls of the canal presented a gray pigment; they were smooth, bloodless, and had the appearance of a cut surface of pulmonary tissue in a state of gray hepatization.

April 19. Evening, pulse 84; temperature 101° . This was the last time that the temperature was found to be higher than normal.

April 23. Pulse and temperature normal. Patient slept well, his appetite returned, and breath and sputa had become odorless. The quantity of the expectorated matter which was muco-purulent in character, had been reduced or 2 to 3 ounces in the 24 hours. A small amount of yellow pus which, however, had no odor, was found in the dressings. This same thin yellow pus, mixed with air, was seen in the cavity instead of the former grayish or grayish-red, thin fluid. The walls of the canal were pretty well covered with a layer of granulation tissue.

April 29. The old drainage tubes were removed and substituted by a single one of the size of a finger.

May 1. Patient continued to sleep well, had an excellent appetite, and was gaining flesh. He

coughed once in a while, and during the day he raised about $1\frac{1}{2}$ $\bar{3}$ of muco-purulent sputa. In the area of dullness surrounding the cavity, fine subcrepitant râles were heard.

May 4. The opening into the cavity had contracted considerably. As the drainage tube was found pushed out several times and lying in the dressings, it was not again replaced.

May 11. The wound, which had not been dressed for five days, was mostly healed. A small fistulous tract only remained which communicated with a bronchus; for a few drops of yellow pus mixed with a little air, were forced into the wound when patient was made to cough. On percussion of the chest resonance was obtained in the infra-mammary region down to the fifth rib; in the axillary region down to the sixth. Dullness only remained in an area about two inches in diameter right around the wound. The fine sub-crepitant râles had disappeared; there was normal vesicular respiration all around the fistula, auscultation could detect no signs of a cavity.

In the infrascapular region the respiratory sounds were normal; there were no râles.

May 12. Patient was allowed to sit up a little every day.

June 26. Patient has grown fat and strong and feels well in every respect. A small fistulous opening has remained through which a fine probe passes in for a distance of $2\frac{1}{2}$ inches. When patient is made to cough, neither air nor fluid escapes from this fistulous opening. But a few days ago when I injected a small syringeful of tincture of iodine into the fistula, a violent fit of coughing was thereby produced. The sputum raised by this cough contained brown specks of tincture of iodine, which could be seen with the naked eye. They were proved to be iodine by the starch test. It is evident that this fistula is still in communication with a bronchus.

Patient left the hospital.¹

These cases, though only four in number, showing two deaths and two recoveries, satisfactorily prove to my mind that opening a pulmonary cavity in acute cases of circumscribed gangrene of the lungs, is a justifiable operation. In not one of the above cases did any mischief, or even any inconvenience to the patient, result from the operation. On the contrary, the immediate effect of the operation was a very decided improvement in the condition of the patient, even in the two fatal cases. The distressing cough was, in every one of these four cases, greatly diminished at once. The explanation of this is to be sought not only in the immediate evacuation of the gangrenous contents of the cavity, but also in the fact that the fluid re-accumulating in the cavity, largely ran off through the drainage tubes, whereas, before the operation it had been aspirated up into the bronchi, thereby producing a more or less extensive fetid bronchitis. This bronchitis ceased very rapidly, and there can be no doubt that it, more than the presence of the cavity itself, is the cause of the constant coughing.

The fetor of the breath and sputa diminished sim-

ultaneously with the cough, as would naturally be expected.

As to the cause of non-success in Cayley & Lawson's case, the authors themselves state that the operation was performed too late, and that it might have been successful if performed at an earlier stage of the disease. In Smith's case no autopsy was held, and so nothing can be known as to the cause of its failure. Bull's case and my own have this in common, that in both the cavity closed in about four weeks; that the fever decreased together with the fetor of sputum and ceased in Bull's case in three, in my own case in two weeks after the operation. Cessation of the fetor was followed by improvement in the general condition of the patient, whose appetite and strength returned.

I now wish to add a few words concerning the operation itself and the after-treatment.

Operation.—We should operate as early as possible, that is, as soon as the physical signs of a cavity have become manifest. We should not operate (for anatomical reasons) when the cavity is covered by the scapula or is situated in the apex of the lung. The latter will hardly ever happen in cases of pulmonary gangrene. The location of the cavity should be ascertained by making an exploratory aspiration with a fine needle. The opening into the cavity should be made at the spot where the cavity comes nearest the surface; for not only should we injure as little lung tissue as possible, but we should also have the shortest possible canal into the cavity; the shorter the canal is, the easier will it be to keep it open and to drain off the contents of the cavity. Besides, we may reasonably expect to find pleural adhesions where the cavity is most superficial. These will prevent the operation from causing a pyopneumothorax. It almost seems that, under these particular circumstances, our natural dread of opening a pleural cavity is founded in theory more than in practice. In not one of the 20 cases now on record, in which pulmonary cavities were opened, did such a complication occur.

The incision should be made parallel with the ribs, one or more of which should be resected if necessary. It is essential to have free access to the cavity, as well for the immediate digital exploration made for the purpose of removing large pieces of dead pulmonary tissue, as for the sake of having a wide canal (subsequently) into which sufficiently large drainage-tubes can be introduced. Experience has shown that these canals are liable to contract and close up before the pulmonary cavity has become obliterated.

The canal leading through the pulmonary substance into the cavity, is best made by means of the thermo-cautery, as was proposed by Albert and Koch. Their method has been strongly advocated by Mosler as being superior to any other as yet suggested. The smaller burner of Paguelin's cautery should, as was done in my case, be gradually worked in through the substance of the lung along a detached hypodermic needle, which is used as a guide. The cautery will thus be pushed in not merely in the direction of the cavity, but also in the shortest line existing between the latter and the surface. Working

¹For valuable assistance in the after-treatment I am greatly indebted to Dr. E. P. Davis, then House Surgeon at Cook County Hospital.

slowly with the red-hot cautery will produce no disturbing hæmorrhage from the pulmonary parenchyma, and the canal can easily be enlarged to such size as may seem convenient. Having reached the cavity, we should explore it with the index finger; if large and detached pieces of lung-tissue are discovered, we should remove them with a pair of forceps, being very careful to avoid causing any hæmorrhage by tearing off still adherent shreds of pulmonary tissue. Our knowledge that it is not uncommon for the walls of a gangrenous cavity to bleed considerably, will render us cautious while making the digital exploration.

Whether it is advisable or not to make a counter-opening for the sake of facilitating draining and washing out of the cavity, can as yet hardly be stated. It has not been tried in any of the cases in which operations were performed for pulmonary gangrene. If the counter-opening, in order to be effected, should demand perforation of a thick layer of pulmonary parenchyma, I think most surgeons would hesitate to prolong the operation on this account; for patients suffering from gangrene of the lung are, when operated upon, rather debilitated and exhausted. In my own case, I felt like trusting to one opening, reserving the operation for a counter-opening for some future time if necessity should call for one. Neither in Bull's case nor in mine did such necessity arise.

I forgot to mention one point in connection with the thermo-cautery. A knife, trocar, or some blunt instrument may well be used for opening a cavity which is situated close to the surface of the lung. But in cases where any amount of parenchyma has to be perforated, the thermo-cautery is by far the safer instrument. Now, I do not think it possible to ascertain by auscultation whether a few lines only or an inch or more of lung substance lie between the cavity and the wall of the thorax.

The cavity should be washed out with some antiseptic solution if practicable; but great care should be exercised in doing so. If the cavity communicate with a larger bronchus, and we allow the solution to run in freely, we may, especially during the chloroform narcosis, be so unfortunate as to fill the bronchi of both lungs to such an extent as to produce suffocation. Moreover, injections of even a small quantity of fluid, the nature of which seems to be rather irrelevant, is, in some cases, followed by a fit of coughing sufficiently vehement to produce hæmorrhage from the walls of the cavity. We should, therefore, allow a little fluid only, and that under low pressure, to run into the cavity at a time, and closely watch the effects thereby produced in the patient. It may be that simply draining the cavity without any washing out, is sufficient to secure the beneficial effects of the operation. There is a great difference right here between Bull's case and mine. In Bull's case injection into the cavity never produced any coughing. In my case the smallest quantity of fluid, not only when injected under pressure, but also when allowed simply to flow into the wound with extreme gentleness, was immediately and invariably followed by violent coughing. Mosler in treating other non-gangrenous cavities of the lungs,

has experienced the same thing. He even attributed the death of one of his patients to the injection of a solution of thymol.

The wound may be dusted over with iodoform; this substance has proved effective in preventing the setting up of inflammatory disturbances by fetid fluid discharges coming into contact with the wound, as for instance in operations about the mouth and the rectum. But whether iodoform is indispensable in surgical cases of pulmonary gangrene is questionable. No case has as yet been reported in which the gangrenous fluid of a pulmonary cavity as such did much harm to the external wound; indeed, the fluid contained in these cavities does not seem to be septic.

A heavy antiseptic dressing should, of course, protect the wound. Septicæmia or pyæmia is just as likely to develop from a wound in the lung as from a wound in any other part of the body. But as it is difficult, nay, next to impossible thoroughly to disinfect a pulmonary cavity, the consequences of sepsis would in these cases be disastrous.

After-Treatment.—How often the dressings will require to be changed, will be indicated by the amount of discharge found in them. In the beginning the wound will probably require dressing every day; later on, less often will be sufficient. Daily washing out of the cavity may be desirable, but does not seem to be essential. As mentioned above, it had probably better be omitted if followed by violent coughing. The internal treatment should be carried on in accordance with the principles commonly laid down for the treatment of the disease in question. Disinfecting or deodorizing inhalations, however, whose influence it is difficult to comprehend from a rational a priori standpoint, seem to be rendered superfluous by the operation. If the canal should close before the cavity has cicatrised, I think we need not hesitate to remedy the matter by a second operation. In a favorable case, patient's general health will be far better than it was at the time of the first operation. As yet, however, no case has been published in which a second operation had become necessary.

In conclusion, I shall repeat that, in my opinion, the above cases clearly prove the operation for acute, circumscribed, pulmonary gangrene, to be a justifiable one. When performed in the above described manner, it cannot be said to be attended with any immediate danger to life; moreover, when performed early, we may reasonably hope that it will not only afford temporary relief, but effect a permanent cure. I therefore think that this operation greatly deserves to receive the attention of the profession.

214 East Ohio St., Chicago, Illinois.

A farewell banquet was given to Drs. S. C. Busey, D. W. Prentiss, W. W. Johnston, and J. S. Billings, at the Arlington Hotel, Washington, on June 28, by the Washington Obstetrical and Gynecological Society, on the occasion of the departure of these gentlemen for Europe to attend the Copenhagen International Medical Congress.—*Medical News*.

MEDICAL PROGRESS.

MEDICINE.

ON THE CONNECTION OF ACUTE DIABETES WITH DISEASE OF THE PANCREAS.—Dr. George F. Duffey (Dublin *Journal of Medical Science*) gives a case of acute diabetes of only two months' duration, terminating, after a sudden onset of vomiting and diarrhoea, in death by coma. The patient was a country farm laborer, over six feet in height and well made: his age was 24, but he looked older. The first symptoms of his illness that he noticed were polyphagia, polydipsia, polyuria, and emaciation. While in the hospital he passed in the twenty-four hours from 215 to 170 ounces of highly saccharine urine, of a specific gravity from 1045 to 1040. There was pain in the epigastrium, and tenderness of the abdomen upon pressure. The diarrhoea persisted for a week: the stools were somewhat of a dysenteric character, being very frequent, but small in quantity, of a jelly-like consistence, and extremely fetid. For the first two or three days they contained white masses resembling lumps of undigested caseine, but these disappeared on giving him his milk peptonised. The temperature continued normal up to within three days of his death, when a state of collapse, with cold extremities, supervened. The post-mortem examination showed nothing remarkable to the naked eye, with the exception of the pancreas, which was hypertrophied and felt extremely indurated.

Dr. Duffey, in the further consideration of his case, reviews the statements of various authors to show the connection between disease of the pancreas and diabetes, and finds that in most of the cases cited the organ has been found to be atrophied, rather than hypertrophied. This he explains by the supposition that the atrophy is a sequence of the hypertrophy, and that in those cases of diabetes which have been of some duration the pancreas may at first have been enlarged, and subsequently have been atrophied; but that in acute cases of the disease (like his own) there had not been sufficient time before the patient's death for the atrophic change to occur, which generally follows primary inflammatory enlargement of the gland. His case further bears out the observations of Dr. Stephen Mackenzie—*i. e.*, that all of his cases, with one exception, dying at or below the age of 25 years, died of coma; and that the rapid course of the disease, which as a rule is equivalent to its severity, favors the occurrence of coma. There was also, in these cases of Mackenzie's, a freedom from, or only slightly developed, affections of the lungs.

The consideration of this case is followed by an article, by Mr. P. S. Abraham, giving his notes on the microscopical sections in two cases of diabetes mellitus, of which the case reported by Dr. Duffey constitutes one. Mr. Abraham devotes his attention especially to the condition of the nervous tissue in the cerebellum, pons and medulla. He found in one case, as most marked, numerous masses resembling the so-called "corpora amylacea" and "colloid" bodies, of all sizes, from the bulk of a leucocyte to twenty times the diameter. In Dr. Duffey's case a

few of these masses were observed in the pons, in contiguity to the turgid blood-vessels. The pancreas he found to present the characteristics of carcinoma. He also found the kidneys to show inflammatory infiltration and fatty degeneration, while the lungs gave patches of hepatization, with the usual appearances of pneumonia, which last does not seem to accord with Dr. Duffey's statement of freedom from lung trouble.

THE ANTIPYRETIC TREATMENT OF TYPHOID FEVER.

—There has recently been a pretty thorough discussion of this mode of treatment in the London Medical Society, and carefully prepared papers on the subject have been read by Drs. Coupland, Bristowe and Cayley. The *British Medical Journal* has had a leader on the subject, and Dr. J. O. Affleck has, in its pages, given an interesting summary with some valuable deductions.

This disease owes some of its dangerous characters and damaging effects to the long continuance of pyrexia; the toxic action of the fever poison, particularly on the nervous system, the local lesions in the intestines, and their results in the structural changes and atrophies which render the assimilative processes comparatively inert, form a large part of the morbid process. Since the introduction of the clinical thermometer, attention has been turned in a special manner to the treatment of the pyrexia, with the view of lessening its amount, or at least, of breaking its continuity. For this purpose, various antipyretic drugs of known potency (quinine, salicylate of soda, salicin, kairin, etc.) have been turned to account, and they undoubtedly, in many instances, succeed in bringing down for a time a high degree of temperature. To most of them, however, there exists the objection that their continuance upon which, indeed, their efficacy depends, is often ill borne by the digestive organs, and in some cases they appear to be rather hurtful than otherwise.

The modern employment of the cold bath or cold bathing of the body in fever appears to have been first resorted to in Germany, by Liebermeister, Brand and others. The advantages of this mode of treatment are stated by Dr. Cayley to be as follows:

1. It fulfils the physiological indications that by keeping down the temperature, the febrile metabolism of the tissues, and the accumulation in the blood of the products of this metabolism—and to this Dr. Murchison attributes most of the symptoms of the typhoid state—are much diminished. The granular infiltration and softening of the central nervous system of the heart, of the liver, of the kidneys, of the voluntary muscles, is to a great extent prevented; and, by the stimulating effect of the treatment on the vaso-motor system, that want of tone and general relaxation of the arteries, which is a marked feature of the disease, is counteracted.

2. Where efficiently applied, the treatment produces marked alleviation of the symptoms. When the temperature is kept down, the so-called typhoid symptoms are seldom seen, etc.

3. Complications are rendered neither more frequent nor more severe.

4. The rate of mortality is greatly diminished.

Dr. Affleck discusses these four conclusions in order. As regards the first, he considers that the mere height of the temperature and its effects on tissue-metabolism, will not satisfactorily account for the peculiar symptoms of typhoid fever. A septic process is in operation of which the temperature is but one of the manifestations and not always, *per se*, an accurate or reliable one. In addition, in enteric fever there is a distinct visceral lesion, which obviously bears some relation to the temperature. It can scarcely be contended that the mere combating of the febrile action can counteract either of these great factors in the disease. This line of treatment is simply directed to a mere symptom, and is incapable of influencing the still existing cause underlying all the phenomena.

As to the second point, viz., the efficient application of the cold bath treatment, this is limited by requirements which are impracticable in a very considerable proportion of cases. It is difficult to recognize typhoid fever "from the first," and, at least in hospital practice, most of the cases have gone on for a good many days before they come under the cognizance of the physician. Further, its advocates recommend great caution in its use where severe local lesions are indicated, although it is just in such cases that the temperature is often highest.

Thirdly, as to the complications, it is doubtful that pulmonary diseases are rendered much less frequent in view of testimony of a directly contrary character; while as regards intestinal lesions, there is evidence that the liability to these is somewhat increased.

With reference to the last point, a greatly diminished mortality rate, here, too, the proof is inconclusive. First the diagnosis is a matter of uncertainty, the numbers quoted may include morbid conditions which are known to simulate typhoid fever. Then of late years a vast improvement has taken place in nursing, dieting, general hygiene, and in the medical treatment of such cases. Jaccoud asserts "that while the mortality in typhoid under the old method of treatment was about 19 per cent., under the antipyretic mode it is under 11 per cent;" but Dr. Affleck gives the mortality statistics of the typhoid wards of the Edinburgh Royal Infirmary during the 4 years of 1880 to 1883, where in 509 cases there were 60 deaths. Thus, under a non-antipyretic treatment the total mortality was not more than 12 per cent., and if cases moribund when admitted, and dying in less than forty-eight hours, be excluded, the rate is reduced below ten per cent.

Dr. Affleck's objections to this treatment are, the fatigue involved, increasing risks by movements in progressive bowel lesions; and the depressing effects upon the circulation, with the risks of intestinal congestion, hæmorrhage, etc. He therefore contends that the limit of its applicability is a comparatively narrow one.

ALGID COLLAPSE.—Hallopeau, in *La France Médicale*, (*Edinburgh Med. Jour.*), under the name of Algid Collapse, describes a condition characterized by partial or general coldness of the body, accompanied with prostration. He regards the condition as the

opposite of what occurs in fevers, and that it is due to an opposite state of the vaso-motor nerves to that which is present in fevers. The condition is specially observed in cases where the abdominal viscera are the seat of violent irritation, as in cholera, irritant poisoning, intestinal strangulation, and injuries to the abdomen. The lowering of the temperature usually begins in the extremities and face, and may be confined to these parts, but may become general. The contraction of the capillaries in these parts, and the consequent diminution in the amount of heat thus lost, would lead to the expectation that the internal temperature would be raised, which is not generally found to be the case, and this is explained on the supposition that there is a concomitant diminution in the activity of combustion. The pulse is small, the heart sounds are very feeble. The integuments are pale or cyanotic, and covered with a cold perspiration. There is often a degree of dyspnoea not explicable by respiratory lesion. The urine is diminished, and is often albuminous. There are muscular cramps, and the patient suffers from vertigo. He holds that the condition is due to the irritation of the sympathetic centre by the nerves going from the affected part, and through the sympathetic the calibre of the arteries is diminished; that by this means there is venous engorgement and deficient oxidation in the lungs, etc. He believes the condition is not to be explained by a general affection of the circulation, but is due to local disturbances in the circulation and the calorification. And this, he thinks, is proven by the symptoms of the collapse being limited to certain parts, particularly the face and extremities.

FAT CRYSTALS IN FÆCES IN OBSTRUCTION TO THE PANCREATIC DUCT.—Ziehl in the *Archives Générales de Médecine* (*Edinburgh Med. Jour.*), says that fat is mixed with feculent discharges in the case of obstruction to the pancreatic duct in various forms, either as yellowish compact masses, as an oily fluid, or more rarely in the form of acicular crystals united in bundles, and which can only be found by microscopic examination. These crystals had been described by Friedreich in two cases. They are not crystals of tyrosin, as has been maintained by some. Tyrosin crystals are light-brown, and are not soluble in ether, whereas these other crystals are clear and transparent, and are soluble in ether. And he records a case in which the presence of these crystals in the stools helped him to diagnose a case of malignant disease of the head of the pancreas. In it the motions, which were dry, formed, and silver-gray, contained a large quantity of microscopic needle-like crystals, which were either isolated or united in bundles, and which, after being dissolved in ether and then vaporized, left an abundant deposit of fat.

DISCHARGE OF A NECROSSED ARYTENOID CARTILAGE DURING LIFE.—Dr. Schiffrers presented to the Société Médico-Chirurgicale de Liège (*Annales*) an anatomical specimen in two pieces which represented the left arytenoid cartilage of a man 38 years of age, who had suffered from a severe attack of typhoid fever.

The largest of the two pieces was discharged during a threatening attack of asphyxia. Two or three months later, when all symptoms of dyspnoea had subsided, Schiffrers saw lying across the glottis the second portion of the cartilage, which was smaller, and its most delicate extremity pressed a little into the posterior third of the right inferior vocal chord. While attempting to remove it a fit of coughing caused its expulsion. For some days before he again presented some symptoms of laryngeal stenosis. Since this removal of the second piece he has had no trouble, is robust and attends to his ordinary business.

At the last laryngoscopic examination, only the right inferior vocal cord was to be seen. The cord was large, and its functions were normal in the movements of respiration and phonation. During the emission of the sound *e*, it touched the border of the left inferior vocal cord, which was observed with difficulty. At the time of the first examination there were symptoms of unilateral paralysis of the crico-arytenoidei postici. The voice was relatively good, the tone was veiled, but the hoarseness not marked.

SURGERY.

SPINA BIFIDA CURED BY ELASTIC LIGATURE.—Dr. Antonio Turretta has republished from the *Giornale di Clinica e Terapia* of Messina, a case of spina bifida successfully treated by the elastic ligature. His aid was requested for a female child two months old, apparently in good health. She had a tumor as large as a small apple in the middle line opposite the two last cervical vertebrae. It existed at birth, and had since slowly increased. It was supported by a pedicle which measured an inch and a half in circumference. The covering skin was very thin, and of bluish-red color. The tumor was soft, flaccid, and fluctuating. Under strong pressure it diminished somewhat in size; the child cried, and slight convulsive movements were excited in the limbs. No other deformity was present, neither was there paralysis of any organ. An exploratory puncture at the base of the tumor with a trocar gave exit to a thin, transparent liquid of alkaline reaction. The tumor shrank, and the aperture was closed with iodoform collodion. Distension and fluctuation were again perceptible in twelve hours. The tumor having been half emptied by another puncture, its pedicle was constricted with a couple of turns of elastic ligature. At the moment of constriction the child cried, the face became livid, and some clonic movements were excited; but in a few hours the patient took the breast and rested. The next day vomiting was persistent, there was a tendency to coma, and twitching of the upper limbs. The condition on the third day was unchanged, and a small dose of calomel was given each day. All these symptoms had subsided on the sixth day, and the ligature with the tumor separated on the twelfth day, leaving a granulating surface, which gradually contracted. The cicatrix was complete, and the child cured on the twenty-seventh day.

Dr. James Weaver in a note refers to this case as corresponding exactly with one reported by him to

the *Lancet* in 1870, his patient being now a hale and strong boy, the only remains of the tumor being a space about the size of one's palm, covered with long hairs, on his back.

OBSTETRICS AND GYNÆCOLOGY.

THE MEASUREMENT OF THE FOOT AS AN INDEX TO THE SIZE OF THE CHILD.—Dr. Alfred Gönner, of Basel, gives (*Zeitschrift für Geburtshülfe und Gynäkologie*) an attempt to overcome the difficulty in determining the size of the child's head in breech and podalic presentations. His plan is (*Medical Times*) to measure the foot, and from this datum to estimate the size of the child, and, therefore, of the head. He points out that the measurement of the foot is one easily made, and therefore, that his method has in this respect the advantage over the other modes by which it has been proposed to estimate the size of the child, such as measuring its length, and measuring the distance between the fontanelles. Dr. Gönner has measured and weighed 100 children. He comes to this conclusion: that if the foot measures more than 8 centimetres (nearly $3\frac{1}{2}$ inches) in length, the child weighs more than 3,000 grammes (about 5 lbs. 10 ozs.). A foot more than $3\frac{1}{2}$ inches long, therefore, makes it probable that the child is above the average weight, and that there will be more than usual difficulty in the extraction of the head. If the foot be only 7.6 centimetres (about 3 inches) long, a child of moderate dimensions may be expected; and a foot-length of only 7.3 centimetres (a little more than $2\frac{3}{4}$ inches) would justify us in assuming that the child was premature. It is interesting to note, also, that Dr. Gönner finds that the feet of female children are smaller in proportion to the size of the body than those of males. He suggests that the children of the educated classes will probably have relatively smaller feet than those of the laboring classes, but his own field of observation has not supplied him with the materials for testing this point.

The New Orleans *Medical and Surgical Journal* has been re-organized, as far as the editorial department is concerned. Three of the old corps retire, and the remaining two unite with eight others to form the New Orleans Medical Publishing Association. Those who have undertaken this work are active and well-informed young physicians, who promise a good journal.—*Medical News*.

YELLOW FEVER.—One death from yellow fever is reported at Pernambuco by the consul at that place, for the week ending June 7th, and three deaths at Santiago de Cuba for the same period.

Thirteen deaths from this disease are reported by the consul at Rio for the two weeks ending May 31st.

Reports from Ship Island, Sapelo, and Cape Charles quarantine stations indicate a healthy condition of affairs at those stations, with no yellow fever cases in hospital.—*Medical News*.

THE
Journal of the American Medical Association.
PUBLISHED WEEKLY.

THE EDITOR of this JOURNAL would be glad to receive any items of general interest in regard to local events, or matters that it is desirable to call to the attention of the profession. Letters written for publication or containing items of information, should be accompanied by the writer's full name and address, although not necessarily to be published. All communications in regard to editorial work should be addressed to the Editor.

SUBSCRIPTION PRICE, INCLUDING POSTAGE.

PER ANNUM, IN ADVANCE..... \$5.00.
SINGLE COPIES..... 10 CENTS.

Subscriptions may begin at any date. The safest mode of remittance is by bank check or postal money order, drawn to the order of the undersigned. When neither is accessible, remittances may be made at the risk of the publishers, by forwarding in REGISTERED letters.

SATURDAY, JULY 19, 1884.

THE CHOLERA. ITS PROGRESS IN FRANCE. — A cablegram from the U. S. Consul at Marseilles to Secretary Frelinghuysen under date July 10, gives the most reliable information at our command as to the progress of the epidemic during the last week. It says: "The situation at Toulon is unchanged — 14 to 17 deaths daily from cholera. Marseilles is worse. The deaths since Friday, inclusive, are seven, eleven, fifteen, twenty-five, twenty-three, twenty-three. Last night, July 10, twenty-two in twelve hours." Under date July 11, thirty-one deaths are reported at Marseilles up to noon of that day. A dispatch dated July 13, states that up to 9 P. M. there had been 57 deaths in Marseilles and 36 in Toulon during the preceding 24 hours.

Few cases have as yet occurred outside of these cities. Two cases were reported, July 10, at Transylvania, three at Port Mahon in Minorca, and one at Nimes in France. There is no cholera at Rome, and none at Leghorn. The view so strongly urged by Dr. Koch, that the microbe is responsible for cholera, is as strongly opposed by a number of French physicians. They have carefully inoculated a number of animals with Asiatic microbes, and have failed in every instance to give them cholera.

We believe that thus far Dr. Koch's experiments have all met with like results. Until more satisfactory proof to the contrary shall be adduced, it is quite as reasonable to presume that the microbe is simply a concomitant as that it is the *cause* of cholera.

Reports state that Paris is in excellent sanitary condition. No cholera has yet appeared there.

The French Minister of Commerce has written a letter to the Academy of Medicine, which will hold a meeting to-morrow, June 16, asking the Academy "to give an authoritative opinion in regard to the treatment of cholera cases, and the best measures to prevent the extension of the disease." At an early date we hope to present their reply to the readers of the JOURNAL.

INOCULATIVE PROTECTION AGAINST HYDROPHOBIA.

—In the JOURNAL of July 12, under the head of Medical Progress, is an account of a communication by M. Pasteur, concerning his investigations and experiments with the virus of rabies, which is well calculated to create the impression that the diluted virus could be used by inoculation successfully to protect man as well as dogs from liability to attacks of that dreaded disease. In the present number of the JOURNAL our correspondent in Paris refers in his letter to the same subject, mentioning several cases in which the inoculation was tried in patients previously bitten by rabid animals, but which patients all died. Now a medical friend in St. Louis sends us the following item of correspondence, the closing paragraph of which asserts "that the idea of protecting *man* against hydrophobia by inoculation of rabic virus, has for the present, at least, not been investigated." From these various statements, we infer that some time is likely to elapse yet before a bite from a rabid animal can be rendered certainly harmless by inoculation with attenuated rabic virus. The note from our friend is as follows:

"INTERESTING CORRESPONDENCE ABOUT HYDROPHOBIA.—(From the *Courrier Des Etats Unis*). M. Joseph Braman, of New York, has addressed the following letter to M. Pasteur, the illustrious French chemist:

"As a member of the American Public Health Association, I congratulate you on the discovery of a remedy to cure hydrophobia. At the next meeting of our Association I shall have the pleasure of proposing you as an honorary member.

"Will you have the kindness to inform me:
1. Whether quills dipped in the virus could be used, as is being done in vaccination to prevent small-pox?
2. How long will the virus keep and be effective?
3. Can any be sent here which would last several weeks?"

"The following answer, signed by Dr. Roux, was received by M. Braman:

"M. Pasteur instructed me to answer your letter of May 2.

"The journals you have read have probably not given an accurate account of M. Pasteur's last statement, in which the subject of a *remedy against* hydrophobia has not been mentioned. M. P. has simply announced that rabic virus can be obtained of diverse

degrees of virulence, and furthermore, that *dogs* can be *protected* against rabies by inoculation of a carefully selected virus, which is obtained through a particular process.

“It is impossible to send the virus a great distance; further, it must be well understood that the idea of protecting *man* against hydrophobia by inoculation of rabic virus, has for the present, at least, not been investigated.”

“WOLVERHAMPTON AND STAFFORDSHIRE HOSPITAL. CASES OF HEART DISEASE RELIEVED BY BLEEDING.”—Under this title, the *Lancet*, for May 31st, of current year, publishes notes of three cases, reported by W. Collier, M.A., M.B., Cantab., late House Physician. These are interesting from their novelty in this day and generation, when the lancet is almost a discarded instrument. They would seem to indicate, however, that the reaction which succeeded the indiscriminate employment of venesection, is weakening, and that a partial return to the lancet is gaining favor. Let us now examine the cases in question with reference to the blood-letting. All three presented signs and symptoms of venous stasis as a consequence of cardiac weakness. In all three were mitral murmurs, with evident enlargement of the heart. Ten minims of the tincture of digitalis and five grains of the carbonate of ammonium were administered to the first patient every five hours; also, four ounces of gin during the day. Thirty-eight hours after admission the symptoms had so increased in severity, that it was decided to abstract four ounces of blood from the arm. This was at once followed by such marked improvement that at the end of forty days the patient was discharged convalescent.

The second patient received a draught of the infusion of digitalis with ammonium carbonate and spirit of chloroform every six hours for four days. Nevertheless, the symptoms became so urgent on the fourth day as to render venesection advisable. Accordingly, as in the previous case, four ounces of blood were taken from the arm, with the same happy result. In the third case, the symptoms were so alarming at the end of five days, in spite of ten minims of tincture of digitalis and carbonate of ammonium every six hours, that eight ounces of blood were abstracted from the left brachio-cephalic vein, relief from the severity of the symptoms following almost immediately. Both patients were subsequently discharged convalescent, though one, owing to a relapse, had to be readmitted, and shortly afterwards died without a repetition of venesection.

In commenting on these cases, Mr. Collier thinks

the use of the lancet was justified by the urgency of the symptoms due to the extreme engorgement of the venous system, since the overburdened right ventricle was powerless to react to the cardiac stimulants administered until relieved of a part of its load by the blood-letting. Furthermore, the benefit was in all three cases sufficient, in his opinion, to warrant the same proceeding in all similar cases.

It is so simple an operation to draw a few ounces of blood from the arm, and it was followed by such good results in the cases cited, that it may seem hypercritical to question its propriety under such circumstances. Nevertheless, might not the end it subserved have been brought about in another way and without the objections that may be urged against the lancet?

In the first place, the letting of blood entails a loss to the system of not merely serum, but likewise of blood corpuscles: A consideration of importance, since the blood of patients suffering with chronic heart disease is already spanæmic in most cases, and can ill spare any further loss of its globules. Secondly, as the internal medication employed had produced no appreciable effect at the end of several days, much valuable time was lost, for every hour, during which the struggle was prolonged, the heart lost ground. These objections, which may be urged against the final resort to venesection, can not be claimed in regard to prompt and free catharsis. Elaterium, or some other hydrogogue cathartic, would have been capable of so diminishing the surplus of fluid in the venous system, as to have enabled the heart to respond to means employed for its stimulation. And this procedure, without being carried to the extent of depletion or possible gastro-enteritis, would not have been attended by any waste of corpuscular elements, nor probably by a delay of from thirty-eight hours to four days.

Again, the digitalis might have been exhibited at shorter intervals and in much larger doses. Indeed, the administration of a drug should be regulated by its effects and not by arbitrary rules of dosage. Had it in these cases been pushed until its full physiological action had begun to manifest itself, that is, until it had lessened the frequency and augmented the force and fullness of the pulse, it would have compelled the heart to react in spite of the venous engorgement. Free diuresis would have resulted with all its ensuing benefit. Right here it may be remarked, the great reason why digitalis so often disappoints the practitioner is, that he fails to employ it freely enough, being fearful of its cumulative effects. Yet these may be avoided if careful watch be kept over

the pulse and the drug promptly discontinued upon the first discovery of nausea and undue slowing of the heart's contractions. In hospital, if not in private practice, such watchful surveillance is easy.

On the whole, therefore, we think the gentleman of the Wolverhampton and Staffordshire hospital might have rendered the resort to blood-letting unnecessary, had they so chosen.

TENNESSEE STATE BOARD OF HEALTH.—Dr. J. Berrien Lindsley, of Nashville, has been elected to the position of Secretary and Executive Officer of the State Board of Health of Tennessee, which had recently been vacated by the resignation of Dr. C. C. Fite. The position is one involving much labor, directed by a high order of executive ability. The appointment of Dr. Lindsley is an excellent one in all respects.

LITERARY HONORS.—At the recent commencement of the Syracuse University, the honorary degree of LL.D. was conferred by the Faculty and Trustees upon Dr. Nathaniel C. Husted, formerly one of the Vice-Presidents of the American Medical Association and a well-known physician of New York City, etc.

Rutherford College, of North Carolina, has conferred the degree of Doctor of Laws upon Dr. Morris H. Henry, of New York City.

Dr. MacRae of Scotland, recently died suddenly while inhaling chloroform for the purpose of having a tumor removed from his neck by Professor Annandale, of Edinburgh. He was at the middle period of life, and in apparently good health.

SOCIETY PROCEEDINGS.

SOME REMARKS UPON THE TYPE OF TYPHOID FEVER PREVALENT LAST WINTER, WITH PATHOLOGICAL SPECIMENS.

BY GEORGE W. VOGLER, M.D.

Read before the Philadelphia County Medical Society, May 21, 1884.

Mr. President :

The following brief notes may prove of interest to those present this evening.

I desire more particularly to call attention to the unusual prevalence of typhoid fever in our city during the past winter, to the grave type of a majority

of the cases, and to the unusually numerous complications.

These notes refer only to the cases that came under my notice during my service at the German Hospital for the months of January, February and March of this year. I might state in passing that what is true of these cases, is also true of those occurring in my private practice.

During the three months twenty-four (24) cases were admitted into the wards, more than half the entire number of cases treated in that institution last year. As three (3) of the above number were brought into the house in a moribund condition, dying immediately or shortly after their admission, the remarks to follow will not appertain to them.

The balance, twenty-one (21) in number, receiving treatment at our hands, may be divided into the following two classes: mitior, 7; gravior, 14; total, 21. Of the gravior died: uncomplicated, 3; complicated, 2; total, 5 deaths.

For a time there were thirteen (13) cases of typhoid fever under treatment at one and the same time.

My resident, Dr. Weed, kindly tabulated twelve (12) of the fourteen (14) cases of the gravior type, and the more prominent complications noticed in this list are: peritonitis, meningitis, pneumonia, pleuritis, pyuria, rheumatic arthritis, abscesses, otitis media purulenta, parotiditis, and extreme nervous depression.

TWELVE OF THE FOURTEEN CASES OF THE GRAVIOR TYPE.	Nervous Depression.	Hyperpyrexia.	Hæmorrhage.	Vomiting.	Peritonitis.	Meningitis.	Pneumonia.	Pleuritis.	Hydroa.	Arthritis.	Abscesses.	Otitis Med. P.	Parotiditis.
Stelig.....						I							R.
Emery.....		107°		I			I	I				I	R.
Schlipf.....	I	I											D.
Kindsvater.....					I								R.
Nil.....												I	R.
Bühler.....							I	I					R.
Meyer.....	I	I										I	R.
Murphy.....	I	I					I					I	D.
Stoetz.....			I	I									D.
Menzell.....	I								I			I	R.
Holzworth.....	I	I											D.
Kolb.....	I	I											D.

R. for recovered; D. for died.

It will be seen that some of these patients were troubled with more than one of these complications at the same time.

There is no doubt in my mind that a majority of the complications enumerated are chiefly attributable to the extraordinary long siege of inclement weather experienced during last winter.

In eight (8) of the gravior type of cases, the temperature ranged between 104 to 108 degrees. The ages ran from 16 to 34 years.

In some cases in which diarrhœa was not controlled by opium and silver, resorcin in doses of three grains acted very kindly, possessing also the

additional advantage of destroying the fœtor of the stools.

In those cases marked by great nervous excitement or actual delirium, and in which opium or bromides seemed of little or no avail, hypodermic injections of ten grains of muriate of quinia acted apparently as a hypnotic. In passing, I would like to state here that, in one instance, the hypodermic use of this remedy produced an abscess that gave us much trouble to heal. Our statistics at the hospital, however, show this to be a rare occurrence, as out of about 250 hypodermic injections of this remedy in various diseases, abscess resulted in but two instances.

An interesting feature noticed was that whenever the catamenia occurred it was invariably attended by an increase of temperature. In one instance, (Emery), where a relapse was supposed to have taken place, the temperature ran from normal up to 103°, and gradually subsided with the cessation of the menses. This phenomenon was noticed to occur twice in this particular case.

Another matter of interest was that two of the female employes of the hospital were stricken down with typhoid fever, barely escaping with their lives. The duty of one of these women was to empty and disinfect the receptacles for the excrement, etc., and to care for the soiled linen from the typhoid fever wards. The other was employed to wash this linen. I certainly would not like to draw the moral in the first instance: "Do not use disinfectants."

Of course, the treatment of the grave and complicated cases was adapted to suit each individual case. In the milder type of the disease, simple common-sense treatment was used, preferably the mineral acids, 5 or 10 drop doses of nitro-muriatic dil., changing to the dil. sulphuric if diarrhœa became troublesome. Where quinia was indicated, I gave it in small but repeated doses, instead of one or more large doses, rarely giving over 7 grains daily. This method has always obtained the most satisfactory results for me.

Dover's powder for sleep, and opium, silver, ergot and resorcin for diarrhœa and hæmorrhage, were used when necessary; also turpentine, when indicated.

A favorite method of giving small doses of turpentine, quinia, and dil. nitro-muriatic acid together, in cases where the symptoms existing demanded the need of all these remedies, was to use a menstruum of syr. ext. glyc. fld. in the proportion of 2 $\text{f}\overline{5}$ ext. glyc. fld. to 1 $\text{f}\overline{3}$ of syrup, flavored with ol. gaultheriæ. This makes a smooth, pleasant and palatable mixture.

I desire to show the following specimen of perforation of the bowels, the other interesting pathological specimens having been mislaid:

Anna Stötz, æt. 20, domestic, single. Admitted into house January 28, the seventh day of the disease, having had several severe hæmorrhages previous to admission. Some pulmonary complications of an acute nature also present; this rapidly disappeared under proper treatment. On the 30th profuse hæmorrhages occurred, seven or eight during the twenty-four hours.

Treatment: Gallic acid by bowels; opium, ergot and silver by mouth; strychnia hypodermically. By

this treatment hæmorrhage was controlled, and fair hopes of recovery were held out.

About the 5th of February hæmorrhage again suddenly came on, which also gave way kindly to treatment. On the morning of the 10th, sudden collapse with intense pain in abdomen, followed rapidly by death.

The post-mortem examination revealed very extensive ulceration and a perforation situated close to the inner border of an ulcer some two inches in diameter, situated within a short distance of the ileo-cæcal valve.

ANNUAL MEETING OF THE UNION MEDICAL SOCIETY OF NORTHERN MICHIGAN.

The annual meeting of the Union Medical Society of Northern Michigan was held at Ionia, April 17, 1884.

There were present at the meeting Drs. Gundrum, H. B. Barnes, Romig, Will. L. Barnes, and Corcoran, of Ionia; McLean, Corey, and Bachman, of Stanton; Bower, Nichols, and Sheldon, of Greenville; Groner, of Big Rapids; Roller, of Edmon; White, of Reed City; Brandt, of Belding; Bailey, of Berlin; Hathaway, of Howard; Smith, of Orleans; and Forsyth, of Lakeview. Four new members were received into the Society.

The following papers and reports of cases were presented: A case of melanosis, by Dr. N. E. Bachman, of Stanton; a case of melanotic sarcoma, occurring at the Big Rapids Hospital, by Dr. F. J. Groner, the surgeon in charge; a case of dropsy of the broad ligament, by Dr. C. S. Sheldon, of Greenville; a case of erysipelas, in which the use of ergot was advocated as a specific in the affection, by Dr. E. O. Smith, of Orleans; a case of pelvic hæmatocèle, by Dr. F. J. Groner, of Big Rapids; a paper with the following title, "Was it a Case of Superfœtation?" by Dr. H. L. Bower, of Greenville; a paper by Dr. A. W. Nichols, of Greenville, on "The Relations of the General Practitioner to Insanity." These reports of cases and papers gave rise to spirited and interesting discussions.

The election of officers for the coming year was held, with the following result: President, Dr. D. A. McLean, of Stanton; Vice-Presidents—Dr. S. V. Romig, of Ionia county; Dr. L. A. Roller, of Montcalm county; Dr. F. J. Groner, of Mecosta county; Dr. L. S. Ellis, of Manistee county; Dr. W. H. Aylesworth, of Kent county; Dr. C. H. White, of Osceola county; Treasurer, Dr. N. E. Bachman, of Stanton; Secretary, Dr. C. S. Sheldon, of Greenville; Board of Censors—Dr. F. Gundrum, of Ionia; Dr. L. S. Griswold, of Big Rapids; Dr. A. L. Corey, of Stanton; Dr. J. H. Forsyth, of Lakeview; Dr. C. S. Ford, of Cedar Springs.

The retiring President, Dr. H. B. Barnes, of Ionia, then delivered an earnest and practical address, advocating more thoroughness and a higher standard of medical education.

The following delegates were appointed to attend the next meeting of the American Medical Associa-

tion: Drs. Groner, McLean, H. B. Barnes, Gundrum, and Sheldon.

On motion, the Secretary was instructed to send a synopsis of the proceedings of the Society to the JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION, for publication.

Adjourned to meet at Big Rapids July 17, 1884.

CHARLES S. SHELTON, Secretary.

ROCKY MOUNTAIN MEDICAL ASSOCIATION.

The thirteenth annual meeting of the Rocky Mountain Medical Association was held in the parlor of the Ebbitt House, Washington, D. C., Wednesday evening, May 7th, 1884.

The president, Dr. J. F. Hibberd, of Richmond, Indiana, occupied the chair.

The following members were in attendance: Drs. N. S. Davis, Pollock, Toner, Bartlett, Sutton of Aurora, Sutton of Pittsburgh, Heighway, Long, Parsons, Harding, Hibberd, Mowry, Findley, Cutter, Strong, Holton and Morris. Honorary members: Mrs. Hibberd and Mrs. Morris.

The minutes of the meeting at Cleveland and the Memorial Record were read by the secretary. The only death reported during the year was that of Mrs. Catlin, an honorary member and widow of a former president of the association. The secretary stated that not a single death of an active member had occurred during the year. Of the original list of 123 members, eighty-one survive.

The annual address was then read by Dr. Hibberd the president. It was a valuable and interesting paper and was listened to with marked attention. As it embraced many reminiscences and striking incidents of the ever memorable journey to San Francisco, a copy was requested for publication. On motion of Dr. Bartlett a vote of thanks was extended to Dr. Hibberd, and the secretary was authorized to have the address printed in pamphlet form for distribution among the members.

A feeling memorial tribute to the memory of Dr. John A. McFarland, prepared by Drs. J. U. Hirschman, A. B. Hovey and H. B. Gibbon, a Committee of the Tiffin, Ohio, Medical Society, was read and ordered to be placed on the minutes.

Dr. George Sutton, of Aurora, Indiana, was elected president, and Dr. John Morris, of Baltimore, secretary and treasurer for the ensuing year.

The association then adjourned to meet in New Orleans the first Wednesday in May, 1885.

JOHN MORRIS, Sec'y.

PROCEEDINGS OF THE NEBRASKA STATE MEDICAL SOCIETY. Fifteenth Annual Session, May, 1883. Plattsmouth, Neb. ROBT. R. LIVINGSTON, Corresponding Secretary.

Contents as follows:

Address of the retiring President, A. H. Sowers, M.D.

1. Report of pistol wound of R. Lung, Diaphragm and Liver, J. Gahan, M.D.

2. Vaccination in America, Horace Chapin, M.D.

3. Cystoid Degeneration of the Kidneys, A. S. v. Mansfelde, M.D.

4. A case of Cystitis, W. O. Henry, M.D.

5. Therapeutic Addenda, A. S. v. Mansfelde, M.D.

6. A case of poisoning by Aconite, A. B. Anderson, M.D.

7. Proper procedure in cases of Obstruction to Labor at Superior Strait, Richard Moore, M.D.

STATE MEDICINE.

NEW ORLEANS QUARANTINE CONFERENCE.

In response to an invitation from Dr. Joseph Holt, President of the Board of Health of the State of Louisiana, a considerable number of representatives from the States of Tennessee, Texas, Louisiana, Mississippi, Alabama, and Florida, attended a Conference in New Orleans, June 2, 3 and 4, 1884.

From advance sheets of the Secretary's report we select the following items of interest:

The following report was made by the committee on the proposition of the necessity of prompt interchange between State and municipal boards of health of information on all subjects relating to public health:

Be it Resolved, That each and every health organization represented in this convention pledge itself to promptly furnish to each other all information in regard to the appearance of cholera or yellow fever or suspicious cases of yellow fever. We recommend that for the purpose indicated in the above resolution, the following groups of symptoms shall be considered to indicate yellow fever and suspicious cases:

I. The following groups of symptoms shall be considered to indicate yellow fever:

Group 1.—A person after a sudden attack has a fever of one paroxysm, attended with marked congestion of blood, stasis of capillaries of surface, conjunctivæ and gums, with a history of probable exposure to infection, and no history of a previous attack of yellow fever.

Group 2.—A person after a sudden attack has a fever of one paroxysm, followed by unusual prostration, albuminous urine, yellowness of conjunctivæ or skin, and having no positively authenticated history of previous attack of yellow fever.

Group 3.—A person has a fever of one paroxysm, albuminous urine, black vomit, suppression of urine, general hæmorrhagic tendency, under circumstances where exposure to the infection is a possibility.

II. *Suspicious cases of yellow fever*.—The following symptoms, associated with a fever of one paroxysm in a patient who has apparently been exposed to infection, and has never had yellow fever, shall be held to justify in either of the six following cases:

1. Suddenness of attack either with violent pain in the head and back, injected eyes and face, or with marked congestion of the superficial capillaries.

2. Want of correlation between pulse and temperature usual to other forms of fever.

3. Albuminous urine.
4. Black vomit.
5. General hæmorrhagic tendency.
6. Yellowness of the skin.

The following cases shall also be deemed suspicious:

7. Any case respecting which reputable and experienced physicians disagree as to whether the disease is or is not yellow fever.

8. Any case respecting which efforts are made to conceal its existence, full history and true nature.

In the event of death of a suspicious case, a post-mortem examination should be made, when practicable. Both before and after death, yellow fever is specially and preëminently characterized by the fact that it is *par excellence* a hæmorrhagic fever, marked by capillary congestion and its sequelæ, hence post-mortem evidence of a general hæmorrhagic tendency in internal organs, especially in the digestive, in preference to the urinary tract, shall be held to confirm the suspicion.

The above were adopted by the New Orleans Medical and Surgical Association and Louisiana State Medical Society.

Respectfully submitted,

GEO. A. KETCHUM, of Alabama,

L. F. SALOMON, of Louisiana,

Committee.

The report was adopted and endorsed as the sense of the Conference.

During the third day's session the Committee on Maritime Quarantine brought in the following report, which was adopted:

"Can an efficient Maritime Quarantine be enforced?"

We can enforce such a quarantine only by devising plans of action such as promise a reasonable, if not a positive assurance of success.

We will understand better the particulars of treatment when we have described the course of a sailing ship through quarantine, no record of sickness on the voyage, a cargo of 30,000 bags of coffee, yellow fever epidemic in Rio, from whence she was cleared. She is brought alongside the wharf at the upper Quarantine Station, where she finds every arrangement for the rapid discharging and reloading of cargo. The crew, with all their effects, are at once taken ashore, where, in a room provided, everything they carry, apparel and baggage, is subjected to powerful disinfection. Their clothing exchanged for other clothing already treated, and this, in turn, disinfected. They are then received at a commodious boarding-house, comfortably prepared for them, there to undergo the prescribed detention. If one should fall ill, he is instantly removed to the hospital, as distant as can be located. In the meantime a full corps of acclimated stevedores are busy engaged in breaking out the cargo and transferring it to the warehouse, already built by the United States Government for that accommodation, there to undergo fumigation. As soon as completely emptied, or at least sufficiently so to permit of thorough cleansing and fumigation, the quarantine tug, a compactly built small vessel, somewhat after the fashion of a

fire tug for harbor protection, is run alongside the ship. A hose, attached to a powerful forcing pump aboard the tug, is let through the forward hatchway down into the hold.

In order to flush the bilge quickly, it might be necessary to take up the limber planks, as a better examination could be had and the real condition ascertained. But whether this is done or not, or the ship be in ballast or not, she can be speedily and thoroughly washed. The pump is started and the washing begins, while the ship's pumps are set to discharging the foul bilge-water. This continues until she is washed clean, not only in the timbers and floor of the hold, but the ceiling and every available part. She is now pumped out, the hose removed, and then begins the disinfection and fumigation. Another large hose attached to a powerful exhaust fan is lowered into the same position as the first. The hatches and every other outlet are closely battened, with the exception of a small ventilating hatchway, either at the bow or stern. A quantity of sulphur is put into the furnace connected with the fan and ignited. The exhaust fan is started and sulphurous acid gas in immense volumes and with tremendous force is driven into the timbers and air-strakes, into every crevice and part of that ship until she is completely filled.

In doing this we displace the mephitic and dangerous atmosphere closed in her when she started from Rio.

We have displaced this with not only a non-infected atmosphere, but with one intensely germicidal—one that destroys organic elements in the air, or on exposed surfaces with instant greediness. As for the fumigating agent to be selected, we may use through this apparatus sulphuric acid gas, chlorine, or the nitrous acid fumes, produced by pouring nitric acid upon copper filings. The fumes produced are so powerful that no animalculæ can exist in them for more than two seconds, and the portholes being closed for twelve hours, the process cannot fail to be effective.

After a few hours the hatches are removed and pure air is driven in to facilitate clearing the ship of the fumes. She is reloaded and, with her captain on board, in order not to vitiate the insurance, proceeds at once to the city, there to be discharged only by an acclimated gang. Her export freights must be ready. She is at once reloaded and starts on her voyage. If the term of detention of her crew has not already expired, she touches at Quarantine to take on such as have engaged to reship, and puts to sea, with no more detention than was required to cleanse her, with the utmost expedition, which alone was worth the trouble.

Such a method would soon be adopted at tropical ports, before loading, which would greatly lessen the danger and facilitate our work. To avoid complicating the legal point the Board of Health gives the ship the option of remaining at the station with the crew on board the full term of detention, or leave the crew there. Owners will rather leave the crew, and so contract with them, if necessary, as soon as it becomes known that the regulations of this port will

enable ships to lessen their detention. Under such a system days of detention will be reduced to hours, because ships cleansed, disinfected and fumigated in name would be so in fact. There could be no object in holding such a vessel in quarantine, except to serve as a hotel for the crew, which, under the improved system, would be provided on shore; but at present we all agree on a detention of not less than 10 days.

The above plan is submitted as the only one which, in the opinion of your committee, meets the requirements of a quarantine embodying the highest efficiency in the guarantees against importation of pestilence, while at the same time causing the least possible injury to commerce. The present methods of quarantine are, in the opinion of your committee, too vulnerable for criticism, while inflicting upon commerce the extremest hindrance and operating inconvenience to all. They are not reliable in any of the guarantees against the importation of infection.

We would urge upon the boards here represented the rigid execution of all the methods now in vogue to secure such safety as the present system may possibly afford, but that the boards of health in the several States of the Gulf immediately urge upon their several legislative bodies and upon their people the earliest adoption of an improved system of quarantine, in accordance with the foregoing plan.

As to non-intercourse, we can but express the opinion that such a system of rational, strictly scientific quarantine non-intercourse is never necessary to efficiency in a sanitary point of view, and can only be damaging to commercial interests and violative of every interest of humanity, recognizing the fact that the present system, as pursued at the Gulf ports, does not furnish a reasonable security at all times. Exigencies may arise demanding either absolute non-intercourse, or the nearest approximation that can be attained in the extended detention of 30 or 60 days, which is the equivalent.

GEO. A. KETCHUM, Alabama.

R. W. HARGIS, Florida.

A. P. CHAPLIN, Lower Mississippi.

C. D. RICE, Mississippi.

R. M. SWEARINGEN, Texas.

C. C. FITE, Tennessee.

JOS. HOLT, Louisiana.

The Committee on Interstate Quarantine reported the following:

Resolved, That there should be entire harmony and coöperation between the health authorities of the several States.

Resolved, Every State should appoint inspectors on all passenger trains from infected places, and on all steamboats or other river craft on which it may be deemed advisable to have inspectors to see that the quarantine rules are enforced in good faith.

Resolved, Every State should have the right to place inspectors of its own at points within the jurisdiction of any other State, and upon railroad trains and river boats within the limits of such jurisdiction. Inspectors coming under this head should be allowed all reasonable facilities for obtaining information and for the transmission of the same; and should comply

with the quarantine regulations of the State or locality in which they are acting.

On local or municipal quarantine yellow fever or cholera having been introduced into any community, particularly into any city or town, earnest efforts should be made to confine the disease within the smallest limits—that is to say, to prevent its dissemination through the community. To this end the infected house or locality should be rigorously isolated and disinfection should be employed according to the most approved methods.

JEROME COCHRAN, Alabama.

G. B. THORNTON, Tennessee.

W. E. ANDERSON, Florida.

R. M. SWEARINGEN, Texas.

J. M. TAYLOR, Mississippi.

L. F. SALOMON, Louisiana.

There was great unanimity of feeling displayed throughout the meeting, and, if the Boards intrusted stand together, much will be accomplished.

ILLINOIS STATE BOARD OF HEALTH,
OFFICE OF THE SECRETARY,
SPRINGFIELD, July, 1884.

DEAR SIR:—At the recent meeting of the State Board of Health, held in Springfield, July 2 and 3, 1884, the following resolution was adopted:

Resolved, That while epidemic cholera may be excluded from this country by thoroughly enforced quarantine regulations, yet the best attainable sanitary condition of every locality in the State should be secured, so that in the event of Asiatic cholera effecting an entrance, notwithstanding quarantine, the disease may be met and fought under the most favorable circumstances; and the Secretary is, therefore, hereby authorized to take such action as, in his judgment, will most promptly obtain a thorough sanitary organization of the State, and the adoption and enforcement of the measures necessary to improve its general sanitary condition.

It is entirely possible that we may escape a visitation of Asiatic cholera this year, although there is yet plenty of time for the disease to reach our shores before cold weather. But even if there were no danger from this source, it should be remembered that everything which is done in the direction of sanitary improvement benefits the general health, reduces the amount of sickness, and lessens the death-rate. An obvious duty, therefore, rests at all times, but more urgently at present, upon those charged with the administration of public-health affairs, to take such steps as may be necessary to remedy any defects in the existing sanitary status.

To this end a general inspection of the entire territory under your jurisdiction should be made forthwith; and all nuisances, or other conditions injurious to the public health, which may be disclosed by such inspection, should be promptly abated. Especial attention should be paid to—

FIRST.—*The condition of the water supply.*

SECOND.—*The disposition of night-soil, garbage and sewage.*

THIRD.—*The cleansing of streets, alleys, and other public places.*

FOURTH.—*The supervision of food-supplies, and of market-places, slaughter-houses and similar establishments.*

FIFTH.—*The general sanitation of every house and its surroundings.*

1. Water is one of the commonest mediums through which cholera spreads; but, aside from this, typhoid and malarial fevers, diarrhoea, dysentery and other diseases, are caused by impure and polluted water. Hence the necessity of protecting the supply from contamination by surface-washings and drainage of filthy soil or premises, or of wastes from manufacturing establishments, or by seepage through the ground from privy-vaults, cess-pools, etc.

2. Night-soil, garbage, sewage, and all other forms of decomposing organic matter, are highly prejudicial to health, and their foul odors are indications of danger. The various methods for their proper disposal, so as to render them harmless, are well understood, and should be enforced according to the varying conditions of each locality.

3. Clean streets and alleys, and gutters properly drained and kept free from unsightly and filthy accumulations, are of even greater importance during the heat of summer, than at other times. The healthy condition of the atmosphere of a locality largely depends upon the condition of its thoroughfares.

4. The rapid decomposition of most articles of food during hot weather—the tainting, souring, wilting or rotting processes—and the derangements of the stomach and bowels caused by the use of such food, indicate the necessity for special supervision at this time, of all food-supplies, and of the places where they are prepared, stored, or disposed of.

5. The foundation of healthy living is, obviously, the individual home and its surroundings. Houses, cellars, yards and out-buildings should be carefully inspected, and all accumulations of garbage, refuse and filth of every description should be removed, or, where this is not practicable, they should be rendered harmless by appropriate treatment. No house or premises can be healthy without proper drainage. If this is not secured by sewers or underground drains, then recourse should be had to surface drains, so as to prevent the possibility of stagnant water under the dwelling or in its vicinity. Cellars should be dry, clean and well-ventilated, so that they may not generate foul air to be drawn up through the house.

It is desired that this work of inspection, and remedying of evils and defects, be begun at the earliest practicable moment; and a preliminary report be made to this office, covering in a general way, the existing sanitary condition, and the measures adopted and enforced for its improvement.

In connection with this report, information concerning your public-health provisions is also desired. I have, therefore, to request the names and addresses of your health commissioner, health officer, members of the board of health, or kindred officials; and copies of your health laws, ordinances, rules and regulations, etc.

With this information from every part of the State, the Board will be able to secure concert of action, and to direct, intelligently and efficiently, whatever measures may be found necessary should, unfortunately, any emergency arise requiring such action.

Forms of health ordinances, adapted to the various organizations of villages, towns and cities in the State, are now being prepared, and copies of the same will be furnished on application.

Confidently anticipating your early attention to this matter, in the interest of your community, I am,

Very respectfully, JOHN H. RAUCH,
Secretary.

FOREIGN CORRESPONDENCE.

PARIS LETTER.

PARIS, June 11, 1885.

It is difficult to reconcile the arguments lately propounded by M. Pasteur at the Academy of Sciences, and subsequently at the Academy of Medicine, with the facts elicited by the report that was read on the 16th of February last at the Council of Salubrity of the Seine, of which M. Pasteur is a member, on the cases of hydrophobia or rabies that were observed in human subjects in the department during the years 1881, 1882 and 1883. These cases amounted to 33. Of this number, 24 were treated by various methods, and nine were treated by inoculation with the rabie virus, viz.: One by Drs. Dujardin, Beaumetz and Lannelongue, one by Dr. Bouchard, two by persons not named, one by M. Roux, one of M. Pasteur's pupils, this inoculation being consequently practiced in strict conformity with M. Pasteur's mode of proceeding, finally four, or rather five, practiced by M. Pasteur himself. All 33, men, women and children, died, the inoculated as well as the non-inoculated, and in the same lapse of time. And it is after such deplorable results that M. Pasteur lately declared before the academies with some assurance that the first series of experiments that he undertook gave him great hopes that, if a person bitten by a mad-dog were inoculated during the stage of incubation, he would with certainty be protected against the development of the disease, and a fatal issue would thus be averted.

Attempts are from time to time made to rehabilitate the practice of bleeding (here used in a general sense) as a therapeutic agent in the treatment of disease. In France the practice of general or local blood-letting is all but entirely exploded, so much so that the present generation of medical students scarcely know how to use a lancet for the purposes of venesection. Cupping is sometimes employed, but leeches are now so rarely seen that they are almost looked upon as simple curiosities of natural history. Professors Hardy and Peter, of the Paris Faculty, however, still practice blood-letting in most of the cases in which it was formerly resorted to. In Belgium an attempt is being made to revive blood-letting, and Dr. Borlée, in a very able address at the Academy of Medicine of Brussels, lately protested in strong terms against the abandonment of, in his opinion, such a valuable remedy in the treatment of disease, observing at the same time that it was simply due to the impulse of fashion, for after having in former times employed blood-letting to excess, it is now almost considered malpraxis to draw blood from a patient even where it is clearly indicated. This change is said to be justifiable by the teachings of modern experimental physiology and therapeutics, which argument, however, does not hold good in all cases. For instance, Dr. Borlée was struck with the great mortality from pneumonia for some years past, which he is convinced is due to the suppression of blood-letting, and asserted that at the commencement

of his hospital career, every pneumonic patient was treated by the anti-phlogistic method, in which, of course, bleeding is included. The cases of non-success were rare. He did not believe in the change alleged to have taken place in the medical or individual constitutions, and after disserting on the physiological action of blood-letting, which consists in diminishing vascular tension and increasing the activity of the circulation, he advocates its employment in all cases of congestion and inflammation, in which no other method would be of much avail. Dr. Borlée recommends bleeding during the paroxysms of asthma, unattended with cardiac complications, in which cases nothing is more efficacious, and the almost instantaneous relief it affords is always most marked. Plethora, the divers congestions produced by albuminuria of pregnancy, apoplexy, nephritis resulting from scarlet fever and other affections, and hæmorrhages in general are, according to Dr. Borlée, so many definite indications for blood-letting.

Dr. Borlée, I am afraid, will not obtain many proselytes, as the teachings of the modern school tend to a practice almost diametrically opposed to that advocated by him. The Academy of Brussels is so impressed with the advantages of blood-letting, that last year it proposed a prize for the best essay on the subject, but none was forthcoming. This year another appeal is made to the profession, and another prize offered by the Academy for the best essay "On the physiological action of local and general abstraction of blood; its indications and contra-indications in the treatment of disease." The value of the prize is 1,500 francs, and the competition, which I presume is open to all nationalities, as nothing is stated to the contrary, will be closed on the 31st of December, 1885. The conditions laid down are: The memoirs, legibly written in Latin, French, or Flemish, should be addressed, post-paid, to the Secretary of the Academy of Medicine, at Brussels.

Exclusion from competition will be imposed on the following grounds: 1. The memoirs which do not fulfil the conditions above mentioned. 2. Those whose authors will be made known, directly or indirectly. 3. Those which may have been published, either totally or partially, or had been presented to any other learned body. 4. Those that reach the secretary's office after the time fixed. Moreover, the Academy exacts that quotations should be rigorously noted, and the competitors are expected to indicate the editions and pages of the books from which the quotations are borrowed. The memoirs should bear only a motto, which should be copied on a sealed envelope, enclosing the names and addresses of the authors. The envelope attached to the memoir crowned will be opened in public by the President, who will immediately proclaim the name of the author.

Dr. Borlée, at whose instigation the above subject is proposed for competition, is Professor of Clinical Surgery at the University of Liege, but he would not allow this to prevent his proposing what may be considered strictly a medical subject. He thought that the time had arrived when the line of demarcation should no longer exist, as medicine and surgery are not two distinct sciences, but they simply constitute

two branches of the same science. The unity of the two branches is discovered in every-day practice, where the therapeutics of the so-called surgical affections are blended with those of medical cases, and vice versa.

ALEX. BOGGS.

DOMESTIC CORRESPONDENCE.

FROM WASHINGTON.

MEDICAL MATTERS BEFORE CONGRESS.—The mention made in a previous letter, page 698, of the appropriations recommended in the House of Representatives for the contingent epidemic fund and for the support of the National Board of Health, should have been accompanied by the following:

Mr. Riggs, from the Committee on the Public Health, submitted the following report: [To accompany bill H. R. 2785.]

The Committee on the Public Health, to whom was referred the bill H. R. 2785, have carefully considered the same and the important subjects which it involves, and have the honor to report:

That they do not think it would be wise to confer upon the National Board of Health the broad powers which they would possess if this bill should become a law. We believe it will be best to leave the management of the quarantine and epidemics where it rests now. The Secretary of the Treasury in his last annual report assures us that the present plan has furnished good results, and we are convinced his statement is correct. Yet we are of the opinion the National Board of Health should be preserved, and that it should be provided with reasonable means to pay the expenses of its existence and of such work as properly comes within its sphere.

Therefore your committee recommend that the bill mentioned do not pass.

They further recommend the passage of the accompanying resolution.

June 23, Mr. Moulton, of Illinois, introduced a bill (H. R. 7426) to incorporate the National Eclectic Institute and Sanitarium of the District of Columbia. The bill names twelve individuals, men and women, who are to conduct an institution, the practice of which shall be the scientific use of electricity, combined in cabinet vapor, and medicated baths of magnetism, Swedish movement and nutritive cure, upon the brain, the nerves and the blood. The institution is to embrace a dietetic and hygienic department, designed to invigorate and restore mental and physical exhaustion. The poor will be provided for if the benevolent will contribute enough to pay their expenses; and the institution is to hold and use property, personal or real, sufficient for its full accommodation, convenience and support, which shall be exempt from all taxes and assessments.

Irrespective, of course, of what goes before, I would like to state that the *Medical Times and Gazette* of June 7th has a very interesting editorial headed, "A Hotbed of Quackery," referring to London and the operations there of two prominent

irregulars, one a Count Cesare Nattei, of Bologna, a man of birth and property; he has found two remedies in Italy, by which he can cure all diseases, even cancer; he has cured thousands he says, in different cities, and for many years he has maintained out of his own funds a hospital at Bologna, for the treatment of the poor. He is distinctly a humoral pathologist. There are two main fluids in the body, blood and lymph, and all diseases arise from the perversion of one or both; there are also two main remedies, and if your disease will not yield to "Antilinfatici," it will assuredly succumb to "Anti-Angiotici." His name as the author of the new "electro-homœopathy" is mentioned with sympathetic respect in many an aristocratic home. The other is an ex-lieutenant of the Swedish army, who adopts a modified form of Zander's system, in a large house in one of the best West-end squares of London, and the number of patients who daily submit to these manipulations is described as very considerable. He will knead your head for epilepsy, pummel you for locomotor ataxy, tweak you for paralysis, and in fact manipulate you for any and every disease. He, too, has a plausible theory, and is in a position to appeal with success to the wealthy and so-called educated classes. The *Times* concludes its editorial by consoling practitioners with the assertion that their patients will come back to them after a certain period of trial culminating in disappointment, but thinks that if doctors would never try to make people think that they know much more than they do, but would honestly confess their ignorance when they are puzzled, their patients would have less reason to confound them with irregular practitioners, and less temptation to fly from one to the other. Please excuse this digression if it be so considered, but it seems to be pertinent and suggestive.

We are to have a new medical college. We have only three now, and this will make the much-needed fourth. The other three think there are two too many already. Put them all in one, and the revenue would hardly buy the necessary materials for teaching. This is to be a department of the National University so long talked of, and the medical gentlemen who, by their enterprise, will at least earn the title of professor, are as follows: John T. Winter, M.D., Professor of Materia Medica and Therapeutics, and President of the Faculty; Howard H. Barker, M.D., Professor of Obstetrics and the Diseases of Women and Children, and Dean of the Faculty; Thomas E. McArdle, M.D., Professor of Surgery and member of the Board of regents; Samuel S. Adams, M.D., Professor of the Theory and Practice of Medicine; G. Wyeth Cook, M.D., Professor of Physiology; Middleton F. Cuthbert, M.D., Professor of Chemistry; George Wm. West, M.D., Professor of Anatomy. The first course of lectures will commence October 1 next. This University has already had a law department in operation for some years.

I would like to suggest, Mr. Editor, that you give us your views upon the influence which the new rule adopted by the Association, allowing all medical men of good standing in their respective Societies, by presenting the proper credentials, to become perma-

nent members of the American Medical Association, should have upon the selection of delegates to the same body in the future. It has been common up to this time for men who have proved their efficiency in the past as delegates, and therefore have become thoroughly familiar with the workings of the Association, to stand aside to make room for others to take their places, and become in turn permanent members. Is it not the time now for insisting upon a more stable and permanent organization, by showing the various societies the importance of electing the same delegates, year after year if necessary, when they have shown their active interest in the Association, and ability to fill these places satisfactorily? In other words, to resort to a more careful selection for the future.

W. L.

NERVE FUNCTIONS.

On the following postulates we desire the calm and careful consideration of those conversant with the blood supply and microscopic anatomy of the brain, that our interchange of views may be beneficial as well as entertaining to the readers of the *JOURNAL*.

We hold that there is no such thing as reflex action. That all nerve force is from center to periphery, and that which we term reflex action is but the cognizance of nerve-waste, and that the involuntary motion of avoidance is the result of ganglionic cell supply of same. Constant irritation of the peripheral end of a nerve calls for continued supply, thereby an abnormal determination to its center and finally inflammation, erroneously termed *transferred* irritation. The gray through its oxygen, being the true dynamic matter, is but fuel for future brain waste, and any impediment to its transit through its schwannian structure destroys its use, as is seen in sclerosis, insanity, perverted sensations, neuralgia, as well as in the beneficial results of nerve-stretching and counter-irritation. That it is the seat of any intellectual faculty, is destroyed by the frequent loss or absence of a part or parts which was not even suspected during life, but if viewed as a protein nucleated cell, which by the constant calls of the economy become fissiparously multiplied, elongated and enveloped by the white substance of schwann, is carried to its termination to supply nervous sensation or force, would explain its invariable and super-abundant connection with the centers of all nerves of rapid or constant use or action, as thalamus, corpus geniculatum and striatum and pineal body. And to those following the ingenious researches of Gaul in the plurality of brain functions, a more likely reward in determining the depth to which the pia mater dips into the substance in the centers of Ferrier, than by any convolution or tubercle on the outer table of the skull. Ferrier, in the demonstration of his centers, conclusively proves such plurality, and if these be viewed as the *infundibular origin* of a special nerve, and the heart (not the pineal body as according to Descartes) as the seat of the soul in man, and knowing its intimate connection through the pneumogastric nerve with the cerebrum, cerebellum, chord and

sympathetic system and find a very plausible center for the *secure* and *ready* manifestation of every psychical impulse. More anon, SIGMA.

NECROLOGY.

COLEMAN, WILLIAM CLARK, M.D., was born in Clarksburg, Indiana Co., Pa., Nov. 29, 1839, and died at the residence of his mother near Livermore, Pa., May 4, 1880. His parents were of Scotch-Irish extraction. He was educated at Elder's Ridge Academy, Pennsylvania, and Saltsburg Academy in the same State. At the outbreak of the civil war his medical studies were unfinished and he preferred the duties of a soldier to those of a subordinate in the medical department. He accordingly enlisted as a private in Company D., Eleventh Regiment, Pennsylvania reserve vols., Aug. 30, 1861, and served in the field throughout the war, taking part in twenty-six battles, including those of Fredericksburg, Gettysburg, the Wilderness, Spottsylvania, Petersburg, Five Forks and Appamattox, C. H., at five of which he was wounded, in the right elbow, in the left arm, in the left hip, and in the chest, respectively. He was early promoted for gallant and meritorious conduct to the rank of First Sergeant, next to that of First Lieutenant, and then to a Captaincy. On several occasions he was the subject of special mention by commanding officers for bravery in battle as well as for efficient service rendered the wounded on the field after battles. At the close of the war he continued his medical studies, attending his first course of lectures at the Jefferson Medical College, followed by a second and third course at the Long Island College Hospital, where he graduated June 28, 1868. He was married May 18, 1869, to Isabella J. Richey, of Livermore, Pa., who died June 6, 1876. The result of this marriage was two children, a daughter and son, the latter dying a few months prior to his father. He located first at Livermore, Pa., but removed after a short time to Latrobe, Pa., where he continued to reside.

Dr. Coleman was a member of the Westmoreland County (Pa.) Medical Society, having been its President in 1874. He was also a member of the Medical Society of the State of Pennsylvania, and of the American Medical Association. He made a study of hygiene, on the chief points of which he lectured extensively and acceptably before audiences more or less popular. In 1872 he delivered a complete course of lectures on physiology before the students of the Blairsville Academy, and afterwards to the students of the Blairsville Female Seminary. He contributed articles on various subjects to the medical journals and transactions of the State Society. On the 11th of August, 1871, he was commissioned Lieutenant-Colonel and Surgeon-in-Chief of the National Guards of Pennsylvania, Eighth Division, and re-commissioned August 1, 1876. He was present at the Centennial Encampment throughout, and participated in the public demonstration of the Pennsyl-

vania military in Philadelphia, Aug. 10, 1876. During the railroad riots of 1877 he was one of the leading surgeons in camp at Pittsburgh. Early in life he embraced the faith of the Presbyterian church, of which he continued a consistent member.

An indomitable will and ambition constantly evinced themselves during both his military and professional career. Dr. Coleman enjoyed an extensive practice and was respected and beloved by all who knew him.

I. P. KLINGENSMITH, M.D.
Blairsville, Pa.

TUCKER, GEORGE GREENVILLE, M.D., born at Warren, Mass., in 1834, died at his residence in Westfield, Mass., August 19, 1883, of heart disease. His parents removed to Cambridge, Mass., during his childhood, where his father died, leaving the subject of this sketch at the age of twelve years dependent upon his own resources to obtain an education. He determined early in life to enter the medical profession, and at the age of seventeen entered the Massachusetts General Hospital as house officer, remaining three years, pursuing at the same time his medical studies in the Tremont and Harvard Medical Schools, graduating at the latter institution with distinction at the age of 20 years. Desiring more extended study and greater advantages before entering upon his professional career, at great personal sacrifice, he went abroad, spending some time in Paris. While in Europe he arranged to go on the medical staff of the Russian Army fighting in the Crimea; but peace came and he returned to America. He opened an office in Boston, where he remained a year, when a more favorable opening induced him to remove to Westfield, Mass., where he spent the remaining 27 years of his life in active practice, being wholly absorbed in his profession, caring for no other distinction than to be a skilful practitioner of medicine, consequently he was eminently successful both as a physician and surgeon. During the civil war he was obliged by circumstances to remain at home; but besides sending a substitute he gave public notice that he would attend the families of soldiers in town free of expense to them during the war, which duty he faithfully performed for four years. In 1873, his health being seriously impaired, he went abroad with his wife and little boy, remaining 15 months, spending one winter in Berlin. On returning home improved in health, he entered again with enthusiasm upon his beloved work, soon acquiring a large practice, which he handled till the day of his death, though suffering severely at times from neuralgia during the last years of his life. Dr. Tucker enjoyed the confidence and esteem of his professional brethren, and his social qualities made him many warm personal friends among his fellow-citizens. He married Miss Langdon, grand-daughter of the late Abner Past, of Westfield, Mass. He was an honored member of the Congregational Church, of the Massachusetts Medical Society, and of the American Medical Association.

JOHN H. GILMAN, M.D.

Lowell, Mass., July 9, 1884.

OFFICIAL NOTICE.

ANNUAL DUES from members of the Association—*Five Dollars* per annum—are payable directly to the Treasurer. Such payment entitles them to receive the JOURNAL of the Association for one year.

SUBSCRIPTIONS TO THE JOURNAL from those who are not members should be forwarded to the office of publication, Chicago.

BACK VOLUMES OF THE TRANSACTIONS may be procured, at reduced rates, by addressing the Treasurer.

THE INDEX to the 33 Volumes of Transactions will be forwarded, postpaid, on receipt of *One Dollar* by the Treasurer.

According to a resolution passed May 9, 1884, at the Washington meeting, continuous payment of Annual Dues is required, to retain permanent membership.

RICHARD J. DUNGLISON, M.D.,

Treasurer.

Lock Box 1274, Philadelphia, Pa.

A FINE CHANCE.

A beautiful, healthy home, fine office, and fair practice of fifteen years' standing, in a pretty and clean city, a county seat of seven thousand in central Ohio; buildings brick; house has seven rooms; office three; lot nearly half acre; good barn, well, cistern, and lot all fruited of different varieties. Situated near the center of town on one of the main streets. Terms—\$2,800 cash, or \$3,000 in short payments. Will give immediate possession and retire from the city and practice. Address P. O. Box No. 605, Circleville, Ohio.

OFFICIAL LIST OF CHANGES OF STATIONS, AND DUTIES OF MEDICAL OFFICERS, OF THE UNITED STATES MARINE HOSPITAL SERVICE, APRIL 1 TO JUNE 30, 1884.

Bailhache, P. H., Surgeon, detailed as Chairman of Board to examine candidate for appointment into the Revenue Marine service, May 17, 1884.

Vansant, John, Surgeon, to proceed to Empire City, Oreg., as inspector, April 2, 1884.

Hutton, W. H. H., Surgeon, granted leave of absence for twenty-five days, May 14, and June 9, 1884.

Miller, T. W., Surgeon, granted leave of absence to attend the meeting of the American Medical Association, May 1, 1884; to proceed to Pittsburgh, Pa., Ashtabula, Ohio, Buffalo, N. Y., and Detroit, Mich., as inspector, May 10, 1884.

Wyman, Walter, Surgeon, detailed to represent the Marine Hospital Service as delegate to the American Medical Association, April 17, 1884; detailed as member of Commission to inspect United States buildings at quarantine station, on the Delaware river, June 16, 1884.

Austin, H. W., Surgeon, granted leave of absence to attend the meeting of the American Medical Association, May 2, 1884.

Gassaway, J. M., Surgeon, when relieved by P. A. Surgeon Mead, to proceed to Portland, Maine, and assume charge of the service, April 16, 1884; granted leave of absence for thirty days, May 28, 1884.

Stoner, G. W., Passed Assistant Surgeon, when relieved by Surgeon Gassaway to proceed to Cairo, Ill., and assume charge of the service, April 16, 1884; when relieved by Surgeon Gassaway to report in person to the Surgeon General, June 20, 1884.

Irwin, Fairfax, Passed Assistant Surgeon, granted leave of absence for twenty-one days, June 19, 1884.

Mead, F. W., Passed Assistant Surgeon, when relieved by Assistant Surgeon Devan to proceed to Philadelphia, Pa., and assume charge of the service, April 16, 1884; detailed as recorder of Board for physical examination of candidates for appointment as cadets in the Revenue Marine Service, May 20, 1884.

Carter, H. R., Passed Assistant Surgeon, to inspect unserviceable property at the San Francisco Hospital, May 24, 1884.

Wheeler, W. A., Passed Assistant Surgeon, to inspect unserviceable property at the Chicago Hospital, May 24, 1884.

Benson, J. A., Passed Assistant Surgeon, granted leave of absence for thirty days, April 14, 1884; when relieved by P. A. Surgeon Stoner to report to him for temporary duty, May 19, 1884.

Banks, C. E., Passed Assistant Surgeon, detailed as member of Board to examine physically candidates for appointment into the Revenue Marine Service, May 17, 1884; to inspect unserviceable property at Baltimore, Md., New York, N. Y., and Boston, Mass., May 26 and June 2, 1884.

Bennett, P. H., Assistant Surgeon, granted leave of absence for twenty days, June 28, 1884.

Devan, S. C., Assistant Surgeon, to proceed to Port Townsend, W. T., relieve P. A. Surgeon Mead, and assume charge of the service, April 14, 1884.

Urquhart, F. M., Assistant Surgeon, granted leave of absence for thirty days, May 22, 1884.

Vemans, H. W., Assistant Surgeon, to report to Capt. M. A. Healey for duty as Medical Officer during cruise of revenue cutter "Corwin," April 16, 1884.

Glennan, A. H., Assistant Surgeon, to proceed to Mobile, Ala., for temporary duty during sickness of P. A. Surgeon Goldsborough, June 17, 1884.

APPOINTMENT.

Brooks, Stephen D., M.D., of Massachusetts, having passed the examination required by the regulations, was appointed an Assistant Surgeon by the Secretary of the Treasury, May 15, 1884. (Dr. Brooks had previously served as an Acting Assistant Surgeon from March, 1883, to May, 1884.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT UNITED STATES ARMY, FROM JULY 4, 1884, TO JULY 11, 1884.

Promotion to date from July 2, 1884. Glover Perin, to be Assistant Surgeon-General with rank of Colonel, Andrew K. Smith to be Surgeon with rank of Lieutenant-Colonel, Passmore Middleton to be Surgeon with rank of Major.

PROMOTIONS.

To be Assistant-Surgeon with the rank of Captain, after five years' service, in accordance with the act of Congress of June 23, 1874:

Assistant-Surgeon,	John J. Kane,	June 3, 1884.
"	John M. Banister,	" "
"	Aaron H. Appel,	" "
"	Charles Richard,	" "
"	W. Fitzhugh Carter,	" "

Birmingham, H. P., First Lieutenant and Assistant-Surgeon, from Fort Bayard, N. M., to Fort Bliss, Texas. (Par. 3, S. O. 137, Hdqrs. Dept. of Missouri, July 3, 1884.

LIST OF OFFICIAL CHANGES IN THE MEDICAL CORPS OF THE NAVY, FOR THE WEEK ENDING JULY 12, 1884.

P. A. Surgeon G. P. Lumsden, ordered to U. S. Steamer "Wyandotte," and placed on waiting orders.

P. A. Surgeon R. C. Persons detached from "Wyandotte," and placed on waiting orders.

ON THE CLINICAL STUDY OF THE HEART SOUNDS.

BY AUSTIN FLINT, M.D., LL.D.

Read to the Section on Practice of Medicine and Materia Medica, of
Am. Med. Association, May, 1884.

The volume of the transactions of the American Medical Association for 1858, contains a prize essay by me on the "Clinical Study of the Heart-Sounds in Health and Disease." The term heart-sounds in this essay, used in its conventional sense, was limited to the normal sounds of the heart, and their abnormal modifications, the term, as thus limited, not embracing adventitious sounds, these being distinguished as heart murmurs. The following quotation is from the introductory remarks in that essay: "The clinical study of cardiac affections, which has been prosecuted of late years with so much assiduity and success by observers in different countries, has had reference more especially to the murmurs. On the normal sounds and their abnormal modifications, comparatively small attention has been bestowed. In the course of investigations, having reference to the diseases of the heart, I have been led to think that these sounds have not hitherto received that consideration which their importance claims. Impressed with the belief that a field for clinical research is here open, which requires only proper cultivation to yield results, possessing not only interest, but much practical utility as regards our knowledge of the heart in its physiological and pathological relations, I have for some time been engaged in inquiries directed to the subject. My design in this essay is to contribute the fruits of my researches, and to indicate some of the questions which are to be satisfactorily settled by an accumulation of facts developed by clinical observation."

This quotation is not entirely inapplicable to the subject at the present time. After twenty-six years, it may still be said that here is a field for clinical study not yet fully cultivated, and that the heart-sounds do not now receive at the hands of medical practitioners a consideration commensurate with the importance of their practical bearings. My object in this paper is to supplement the essay to which I have referred, by the results of some further study of the subject, with a view, more especially, to bring it again to the attention of clinical observers.

It is customary to consider the heart sounds as

consisting of two in number, to wit: the first or systolic, and the second or diastolic sound. For convenience in regard to clinical study, it seems to me desirable to recognize five distinct sounds, two of which are diastolic, and three systolic.

The two diastolic sounds are referable, respectively, to the aortic and the pulmonic orifices of the heart. They may be studied separately, as is now generally admitted, by auscultating with the stethoscope, at the left and at the right second intercostal space close to the sternum. These two sounds may be called simply the aortic and the pulmonic.

Of the three systolic sounds, one emanates from the mitral, or the left auriculo-ventricular, and another from the tricuspid, or the right auriculo-ventricular orifice. The third systolic sound has no connection with the orifices of the heart, but is produced by the impulsion of the organ against the thoracic wall. These three sounds may be designated the mitral sound, the tricuspid sound, and the sound of impulsion. The facts stated in my prize essay in 1858 seemed to me then, and they seem to me not less now, to demonstrate the existence of these three distinct elements of the so-called first sound of the heart, and that each may be studied separately. I refer to the essay for the facts, not reproducing them in this paper. I will, however, state where the three sounds are to be separately studied.

Auscultating with the stethoscope (the binaural is to be preferred) over the apex, the intensity, the greater length and the distinctive quality, (which may be called booming¹) of the so-called first sound, as compared with the second sound, (the pulmonic and aortic sound combined) are due to impulsion, that is, the movements of the apex upon the thoracic wall. The sound of impulsion is, therefore, to be studied in this situation. As a rule, this sound does not extend beyond a limited area around the apex. The mitral sound is heard, distinct from the sound of impulsion by moving the stethoscope to the left of the apex in the fourth intercostal space, for a distance sufficient to eliminate completely those characters of the so-called first sound which are referable to impulsion. The maximum of the intensity of the mitral sound is at the situation where the characters of impulsion are eliminated, and generally this situation is but a little removed to the left of the apex-beat. The tricuspid sound is heard distinct from the sound of impulsion, at the interior border of the heart, above the

¹The word *booming* was applied by Walsh to the distinctive quality of the first sound as heard over the apex. This now has been applied, but inappropriately to the second sound.

xiphoid cartilage. Its maximum of intensity is at the situation where the characters of impulsion are eliminated¹.

Not going further into details relating to the existence of the five sounds, and the manner in which they are to be studied separately, I proceed to offer remarks on the clinical study of each one of these sounds under a distinct heading.

1. *The Aortic Sound.*—Incompetency of the aortic valve is generally, if not invariably, separated by a regurgitant murmur. It will, however, be admitted that this murmur, whatever may be its intensity and its characters in other respects, is, in itself, evidence only of the fact of incompetency. The murmur furnishes no criteria for determining the extent to which the valve is damaged. The incompetency may be so slight as to be innocuous, or it may be either small, moderate or great. Information on these points is furnished by either the unaffected intensity of the aortic sound, or the degree of its diminished intensity, and, in some instances, its absence. The importance of the study of the aortic sound, with reference to the gravity, or otherwise, of aortic lesions, is recognized now more than it was twenty-six years ago; but it is still inadequately appreciated by many practitioners. The abnormal weakness of the aortic sound may be estimated by comparison with the pulmonic sound, if the latter be neither intensified nor weakened by morbid conditions pertaining either to arterial tension of the pulmonary artery, or to an increased or diminished power of the right ventricle. A more reliable comparison is with the power of the left ventricle as represented by the sound of impulsion and the apex-beat. The co-existence of increased power of the left ventricle with notable feebleness or absence of the aortic sound, is especially significant as denoting considerable or great damage of the aortic valve.

Murmurs are sometimes spoken of as if they were modifications of the heart-sounds. The latter are always distinct from the former, the murmurs being either added to, or replacing the sounds. If the aortic sound be present, owing to its distinctive valvular quality, it may be recognized, notwithstanding the intensity or other characters of an associated murmur. Rarely, if ever, is the sound drowned by a murmur, however loud or rough, or musical.

The aortic sound is weakened by other causes than lesions affecting the aortic valve. Weakness of this sound is proportionate to the diminution of blood sent into the aorta with the systole of the left ventricle, in consequence of either mitral obstruction or regurgitation, or of both combined. The significance of weakness of this sound is greater in proportion as it is in contrast with the force with which the left ventricle contracts. As evidence of the degree of obstruction or of regurgitation, or of both com-

bined, weakness of the aortic sound, although more regarded now than twenty-six years ago, does not as yet receive the attention which its clinical importance claims.

Abnormal increase of the intensity of the aortic sound is referable to two causes, namely: increased power of the systole of the left ventricle, and increased blood-pressure or tension of the systemic arteries. With regard to the first of these causes, there can be no question as to its agency. Abnormal loudness of the aortic sound is a sign of hypertrophy of the left ventricle, and, to a certain extent, a criterion of its degree, assuming, of course, integrity of the aortic and the mitral valve. Attention has of late been directed especially to an increased intensity of this sound as a criterion of arterial tension, and this latter condition, at the present time, holds an important place in pathology. Clinical observations have led me to distrust the value which some observers appear to attach to the intensity of the aortic sound as evidence of arterial tension. The intensity of this sound varies considerably in different healthy persons. Its relative intensity, as compared with the pulmonic sound, in health, is variable. Exceptionally it is less intense than the pulmonic sound.¹ It is certain that in some cases in which arterial tension is supposed to be an important pathological element, namely, in cases of contracted kidneys, the intensity of the aortic sound is not increased.

The following case is illustrative of this fact:—A patient, about 50 years of age, had had three attacks of uræmic convulsions. The quantity of urine was large, of low specific gravity, slightly albuminous, and contained hyaline and granular casts. He had no œdema except slightly below the eyes. The heart was a little enlarged, and there was no cardiac murmur. The pulmonic sound was distinctly louder than the aortic, the difference in pitch showing that the louder sound was the pulmonic and not the aortic.

In this instance, arterial tension was to be inferred, but, notwithstanding slight enlargement of the heart, and the absence of any evidence of a pulmonary affection, the aortic sound was apparently not increased in intensity.

The recent experiments by Dr. Charles L. Roy, reported in the *London Lancet*, Jan. 26, 1884, show that abruptly cutting off the supply of arterial blood to considerable portions of the body, by ligating large arteries, produces but an extremely slight effect upon the blood-pressure or arterial tension.

Reliance on the intensity of the aortic sound, irrespective of hypertrophy of the left ventricle, as evidence of arterial tension, or on the weakness of this sound as evidence that arterial tension does not exist, must, as it seems to me, lead to erroneous conclusions.

2. *Pulmonic Sound.*—Forty or more years ago, Skoda called attention to an increase of the intensity of the pulmonic sound as a sign of hypertrophy of the right ventricle, in cases of mitral lesions involving

¹To obtain the maximum of intensity of the mitral and the tricuspid sound, the stethoscope is to be moved gradually from the borders of the heart until the sound becomes purely valvular, that is until the characters which belong to impulsion are eliminated. It is easy to find the situations where the purely valvular sounds have their maximum. These situations vary somewhat in different persons in health, and still more in cases of disease. To designate certain circumscribed places as mitral and tricuspid ones, as is done by some writers, is therefore inaccurate and leads to error.

¹In these exceptional instances, the relatively less intensity of the aortic, as compared with the pulmonic sound, may be due to a transient excitement of the heart's action. As will be stated under the head of the pulmonic sound, the intensity of this sound is greater than the aortic when the heart is functionally excited.

either obstruction or regurgitation, or both combined. The intensity of the pulmonic sound is undoubtedly increased by hypertrophy of the right ventricle, but there is another and perhaps a more important factor in the production of this sign, to which attention has been more recently directed, namely, increased blood pressure within the pulmonary arterial system. That notably increased intensity of the pulmonic sound may be due to this factor, irrespective of hypertrophy of the right ventricle, is certain—a fact which explains the persistence of the sign after the right ventricle, in connection with mitral lesions, has become weakened by dilatation.

The pulmonic sound is more or less intensified whenever there is obstruction to the free circulation of blood through the lungs, the co-existence of hypertrophy of the right ventricle not being essential. It is a sign present in cases of pneumonia, capillary bronchitis, asthma, pulmonary oedema, pleurisy, with effusion and hydrothorax. To a certain extent, the degree of increased intensity may be taken as a criterion of the amount of obstruction.

Increased functional activity of the heart intensifies the pulmonic, more than the aortic, sound. The greater intensity of the pulmonic sound is referable chiefly to increased blood pressure within the pulmonary arteries. When the heart is excited by either active exercise or a moral emotion, the pulmonic sound is especially intensified. More blood is propelled into the lungs than can readily pass through the capillaries. If the accumulation of blood in the pulmonary vessels exceed a certain limit, there is dyspnoea; but within this limit the blood pressure is sufficient to intensify the pulmonic sound.

I am not prepared to say how much significance pertains to diminished intensity of the pulmonic sound, as a sign of tricuspid regurgitation, or of the very rare lesions causing tricuspid stenosis, and, also, of weakness of the right ventricle from dilatation or from fatty degeneration. My colleague, Professor Janeway, has called my attention to the frequent absence of the pulmonic sound when, from lesions at the aortic orifice, the aortic sound is abolished. I am not prepared to explain this clinical fact. Of course, damage or destruction of the pulmonic valve must either diminish the intensity of the pulmonic sound or abolish it; but lesions producing these effects are so rare, that the clinical study of this sound, in connection therewith, is not easily pursued, and has but little practical importance.

3. *Mitral Sound*.—The mitral sound, disassociated from the sound of impulsion, is short and purely valvular, like the pulmonic or the aortic sound. Its intensity varies considerably in different healthy persons.

Insufficiency of the mitral valve is represented by a murmur, which, like an aortic regurgitant murmur, simply denotes the existence of lesion, without giving information concerning the importance of the lesion, that is, whether the regurgitating volume of blood be small or large. An abnormal weakness of the mitral sound and its absence, are signs which supply, in a measure, this information. These signs thus have a practical value in connection with mitral lesions.

This statement applies equally to mitral regurgitant and to mitral obstructive lesions. Weakness or absence of the mitral sound associated with either a mitral diastolic or a presystolic murmur, shows that the obstructive lesion either interferes to a greater or less extent, or abolishes the valvular movements which produce the sound.

Exclusive of mitral lesions, the mitral sound may be weakened in consequence of feebleness of the systole of the left ventricle from dilatation or fatty degeneration. Overfilling of the left ventricle as a consequence of aortic regurgitation, has the same effect, irrespective of the force with which the left ventricle contracts. The explanation is, that, under these circumstances, the excursion movements of the mitral curtains may be slight or *nil*, owing to the fact that at the time of the ventricular systole they are not only floated away from the inner surface of the ventricular wall, but are closely in coaptation with each other. When this is the case, the tension of the curtains produced by the pressure of the intra-ventricular blood in the systole, occasions little or no sound.

The intensity of the mitral sound, of course, other things being equal, is proportionate to the extent of the excursion movements of the mitral curtains. If the stethoscope (binaural) be placed directly upon the heart of an animal of considerable size, (*e. g.*, the sheep), the circulation being maintained by artificial respiration, the mitral and the tricuspid sounds are extremely loud and purely valvular, that is, without any sound of impulsion. Both the mitral and the tricuspid sounds have somewhat of a similar intensity in certain cases of anæmia when the heart is excited by exercise or mental emotion. The explanation, as I suppose, relates to the comparatively small quantity of blood within the ventricle when the ventricular systole takes place, together with the quickness and force with which the ventricle contracts.

All who are familiar with the mitral presystolic murmur, must have remarked an intensity of the sound which occurs at the termination of the murmur, that is, the mitral sound. This presystolic murmur, with the rough, vibratory character which it usually has, I believe denotes adherence of the mitral curtains to each other, leaving a bottom hole-like contraction, the mitral curtains remaining flexible. Now, owing to the contracted orifice, the left ventricle, at the time of its systole, is poorly supplied with blood. The movements of the mitral curtains, which I have called the excursion movements, are considerable and the curtains remaining flexible, the conditions are favorable for intensity of the mitral sound. Contrary to the statements generally made by writers, a mitral regurgitant murmur, under these circumstances, is not infrequently wanting. If a mitral regurgitant murmur be present, and the mitral sounds have a notable degree of intensity, it is certain that the regurgitant stream of blood cannot be large, or, in other words, the mitral incompetency is not great.

4. *Sound of Impulsion*.—In healthy persons the sound of impulsion generally predominates over the mitral and the tricuspid sound, at the apex and over

Chas. E. W. Mearns, Boston, Mass.

the body of the heart. The intensity of this sound varies much in different healthy persons. The abnormal modifications of this sound are, increase of its intensity, on the one hand, and on the other hand, either diminished intensity of the sound or its absence. It is to be noted that this sound is not like the valvular sounds endocardial but exocardial; and, like the exocardial murmurs, however loud the sound may be within the præcordia, it is not transmitted beyond the præcordial region. As we can imitate a pericardial friction murmur by placing the palm of the hand over the ear and rubbing gently the dorsal surface of the hand with the finger, so we may imitate the sound of impulsion by pushing the finger with more or less force instead of rubbing gently; and by light percussion with the finger, the sign, known as metallic clic (*tintement métallique*), is perfectly imitated.

It is the increased intensity of the sound of impulsion which gives to the first of the two heart-sounds (as they are commonly reckoned), its loudness, its length, and its booming quality, in cases of cardiac hypertrophy. The sound of impulsion predominates over the mitral sound, whereas, the latter is intensified and predominates when the action of the heart is functionally excited.

Diminished intensity of the sound of impulsion is denoted by diminution of the length and of the booming quality of the so-called first sound of the heart, the mitral sound predominating. The sound of impulsion is lost when the mitral sound is alone heard over the apex and body of the heart. Diminution and extinction of this sound, are signs of weakness of the ventricular systole from dilatation, fatty degeneration and the softening incident to certain infectious diseases. Clinical observers long since attached practical value to these signs, but their importance is perhaps not yet sufficiently appreciated by practitioners in general. Their value in the treatment of fever as bearing on the use of alcoholics and other cardiac stimulants, were especially emphasized by Stokes.

Removal of the heart from contact with the chest wall, in cases of pericarditis with effusion, abolishes the sound of impulsion, the mitral and the tricuspid sound alone accompanying the ventricular systole; and when the sound of impulsion is wanting, as a rule the aortic sound at the apex is louder than the mitral. The sound of impulsion is inappreciable in listening to the foetal heart; the so-called first sound is short and valvular like the second sound.

5. *Tricuspid Sound*.—Weakness and the abolition of the tricuspid sound in consequence of lesions affecting the tricuspid valve and orifice, are not signs of much practical value, owing to the infrequency of lesions in this situation.

Enfeebled action of the right ventricle from fatty degeneration, must occasion abnormal weakness of the tricuspid sound. A thrombus of considerable size formed within the right ventricle, may weaken and extinguish this sound. When the right ventricle is overfilled with blood at the time of the ventricular systole, the tricuspid sound must be weakened, for

the same reason that the mitral sound is weakened when the left ventricle is overfilled.

Hypertrophy of the right ventricle intensifies the tricuspid sound. This is a better sign, by far, of hypertrophy of the right ventricle, than an increased intensity of the pulmonic sound, inasmuch as the latter involves, as an additional factor, increased blood pressure within the pulmonary vessels. In the rare instances of notable hypertrophy of the right ventricle resulting from congenital stenosis at the pulmonary orifice, the tricuspid sound must be considerably intensified. While I am writing, I have before me a specimen in which the pulmonary orifice is contracted to the size of a goose-quill. The right ventricle is hypertrophied, so that its walls are as thick as those of the left ventricle in healthy subjects, and the walls of the left ventricle are not much thicker than those of the right ventricle in healthy subjects, the normally relative size of the two ventricles being thus reversed. The tricuspid valve is normal. The specimen was from the case of a patient, aged 19 years, who died of scarlet fever, and who complained of no subjective symptoms denoting cardiac disease, except panting on active exercise. A very loud systolic murmur had been observed, and it was supposed to be a mitral regurgitant murmur. The patient was not under my observation, but it is certain that the tricuspid sound must have been much intensified; and this sign, taken in connection with the probable absence of the pulmonic sound, inasmuch as the segments of the pulmonic valve were perfectly rigid, would have been valuable as indicating the true seat of the valvular lesion.

In conclusion, the chief object of this paper, as stated at the outset, is to bring again, after the lapse of twenty-six years, to the attention of the profession, the importance of the clinical study of the heart-sounds, as distinguished from the heart-murmurs. As a motive for the preparation of the paper, I confess a desire to refer to my essay to which was awarded a prize by the American Medical Association at the meeting in Washington in 1858. I believe I may assume to have been, at that time, a pioneer in the clinical study of the heart-sounds in health and disease. This study, since that date, has not received from writers and practitioners that attention which its importance claims. If I mistake not, the majority of those who avail themselves of the information to be obtained by auscultation, do not take pains to interrogate separately the sounds emanating from the heart, but, for the most part, limit their auscultatory observations to the murmurs. In the latest French work on the diseases of the heart, published in 1883, the heart-sounds are hardly recognized as furnishing any important signs in diagnosis.¹ Having said this, I would add that in the German work on pathology and therapeutics by Eichhorst, published in 1883, and in the article by Guttman in the Real Encyclopædia, 1881, abnormal modifications of the heart sounds are fully recognized among the data for the diagnosis of cardiac affections. I do not doubt that the time will come

¹Traité clinique et pratique des maladies du cœur, par Michael Peter. Paris, 1883.

when all clinical observers will consider the practical information to be derived from the heart sounds as not less essential than that furnished by the murmurs, taken in connection with the signs obtained by percussion and palpation.

DISCUSSION.

Dr. Richard McSherry, of Baltimore, Md., said:

Mr. Chairman: As an indication of changes in medical acquirement, I may say that when I was a student of medicine in Philadelphia—not very recently—I heard a distinguished professor say he knew nothing of diseases of the heart. The gentleman was very distinguished, certainly not less known to fame, in his day, than his successor, the present honored president of our great Association, but he had not kept up with the progress of his time, for even then the works of Arenbrugged, Corvisart, and Lænnec had taught new and important lessons to the medical world, with which the rising doctors were quite familiar. They at least could not afford to cast ridicule on the “conjuring rod,” as the stethoscope was derively called by some of the “Conscript Fathers” of the profession.

The pulse had been the pre-eminent guide, especially in accordance with the teachings of Bordeu and his followers, from whose investigations and speculations, our fathers were led to believe that through it, they could not only take the measure of the circulation, but that it was a gauge of all diseases in all their modifications. Sphygmics, without the aid of the sphygmograph, had almost the attention since given to auscultation and percussion. The learned doctor of the last century, with watch in one hand while the fingers of the other rested on the radial artery, seemed to find in the throbbing of the artery as reliable an indication of the condition of his patient as of the time of day from the hands of his ponderous time piece.

Now the pulse was, and is, a good indicator, but yet like any other source of information in regard to the vital machine, it may lead to many fallacies, so many, that its real importance came to be underestimated.

Our great master, Lænnec, attached little importance to it by reason of its great uncertainty, saying the ignorant could deduce from it all sorts of indications, while the cleverest could get from it but equivocal conjectures. In truth we know it may deceive us, taken alone, therefore we only rationally use it in conjunction with various other indices of physiological or pathological conditions. It used to be, more than now, a guide in regard to blood-letting, but an improved acquaintance with the central organ of the circulation showed sometimes a strong pulse with a weak heart, and again a vigorously acting heart with a weak pulse (*fictitiè debilis*) and it is from the state of the central organ, and not from the action of the arteries, that we may draw conclusions, *pro* or *con*, in regard to depletion.

We can herein find a scientific guide to practice more reliable than the empirical.

We may now begin to contrast the acquirement of

the professor of the earlier half of the century, with that of the professor of the latter half, the one declaring that he knew nothing of the diseases of the heart, the other showing that no diseases of any other organ or viscus are subject to equally exact diagnosis. I know of no more striking evidence of the progress of medical science.

But although diagnosis is practicable, it is still environed with difficulties. We cannot get patients to correspond exactly with elastic models, which represent one age, one size, and average chest walls. Of two successive patients, one may be an enormously fat elderly lady, and the next a slim youth whose chest walls have but a fraction of an inch between the ear of the auscultator and the heart of the patient.

There are so many accidental perturbing causes, too, to make diagnosis not impossible but difficult. This may be particularly perplexing when there is great functional disturbance with an early stage of organic disease. I was called, a few years ago, to Mrs. S., from New York, at a Baltimore hotel, who had come to reside in our city. I found the lady suffering with great dyspnoea, due to pulmonary congestion with evidences of mitral insufficiency and regurgitation. She appeared to be alarmingly ill. She had passed the menopause by some months as I learned upon inquiry. I prescribed according to the needs of the case, and when questioned by some lady boarders upon leaving the house, I spoke of disease of the heart. In a day or two she was greatly relieved, but in the meantime there occurred a flow rather to be called metrorrhagia than menorrhagia. The great general perturbation subsided rapidly, and upon its subsidence the heart's action showed comparatively little disturbance. I heard from some friends afterwards that my diagnosis had been hardly commented on by the inquisitive critics of the house. I soon lost sight of the lady, who took another medical attendant. About two years subsequently, I saw announced in the morning papers the sudden death of Mrs. S., after a few hours' illness. Whether there was another pulmonary congestion or other cause of death, I never learned, nevertheless I could not doubt that organic disease of the heart was the efficient cause.

It appears, according to Porah's statistics, that in gravido-cardiac disorders, as they are called, more than two-thirds of the cases are those of mitral stenosis, mitral insufficiency, or the two combined. Women affected thus are in great peril from pregnancy and child bearing, and they are advised to refrain from marriage.

“Landouzy mentions the case of a young girl who had been in the hospital under his care, and whom he had advised not to marry, but who disregarded his advice, married, became pregnant, and after a miscarriage, died suddenly in an attack of asystole.” (*Medical News*, April 10, 1884.) In Mrs. S.'s case, although the mother of several children, I presume the perturbation of her general organism was equivalent to that of pregnancy and miscarriage.

We have anæmia (spanæmia) modifying heart sounds, thus it is urged that an elastic contraction of

the orifice of the aorta in anæmic subjects causes a morbid systolic sound at the base of the heart, where no valvular disease can be detected upon post-mortem examination.

Childhood and old age produce their modifications. The evidences of hypertrophy and dilatation are often observed in growing children, which may pass away entirely about the time of puberty, a fact observed by Laennec, and which, from his own observation, induced Dr. Flint to urge caution in regard to giving a prognosis unfavorable and alarming in such cases.

The sharp accentuation of the second sound without valvular disease, or any disease, except in some remote organ, is a matter of perpetual observation. In one of our dispensary patients, but a short time ago, this sign led to an examination, *inter alia*, of the state of the kidneys. A moderate attack of nephritis, with albuminuria, was soon detected, and soon relieved. The cure of the primary disorder corrected the morbid heart sounds which had caused investigation as to the seat of remote disease.

Old age and deep-seated infirmities greatly modify sounds and impulse. I shall never forget my surprise, in my early professional life, upon finding a greatly enlarged heart upon the post-mortem examination of an old man-of-war's man, whom I had seen a few days before death without diagnosing such degree of hypertrophy.

Upon referring to the text which was then my guide, I found the following explanatory passage:

"The heart's impulse in hypertrophy and dilatation is almost lost in some cases of pleurisy, asthma, oedema of the lungs, or of congestion before death." (*Laennec*). The modifying conditions were all there, and as I had had no opportunity of tracing the progress of disease with the patient, but only saw him when near his end, the oversight seemed comparatively pardonable.

Besides the proper heart-sounds, it may not be amiss to refer to sounds induced by the heart's action indeed, but extraneous. Thus, the clinician often notices puffs or whiffs, heard when the contraction of the ventricles forces air out of the portions of lung lying between the heart and the thoracic walls.

There is a condition in which all of the five normal sounds may be heard, but not in the right place. I had an opportunity of seeing, a little more than a year ago, a case of dextro-cardia under the care of my friend, Prof. Chew, at the University of Maryland Hospital.

This was an illustrative case of traction from the left to the right side. The patient, a sailor, had been under my care some months previously with effusion in the right pleura, and moist râles in the right lung. The heart was not then displaced. When subsequently re-admitted into the hospital, on inspection, the intercostal spaces on the right side were depressed, the ribs drawn together, and the lower part of the chest wall sunken in. Measurement showed that the semi-circumference of the thorax was one inch less on the right than on the left side. The impulse of the heart could be seen and felt near the right nipple, the apex beat being a little to the right of the mammary

line. There was perfect dullness on percussion when I used the hammer and pleximeter over the right side; respiratory murmur was replaced on that side by subcrepitant and bronchial râles audible as far as the base of the chest, and at two points the sounds indicated the formation of vomicae. On the left side there was a somewhat exaggerated percussion note, and the respiratory murmur was harsh and puerile, though intermingled to some extent with moist râles. * *

* * Reasoning then by the power of exclusion, we have remaining as the most probable cause of the phenomenon that to which I think it should be assigned, viz.: the contraction of the right lung and right pleura, the lung being adherent to the chest wall; and as it had undergone contraction, together with the thickened pleura it had drawn upon the mediastinum, and thus effected the displacement of the heart. (For the full account of this rare and interesting case see Prof. Chew's report in *Trans. Med. and Ch. Faculty of Md.*, 1883.)

Every one has probably heard various neurotic (perhaps sometimes choreic?) sounds different from any ordinary physiological or pathological sounds which are difficult to express or to explain. Among these anomalies, one gentleman informs us that he has heard with a robust and nervous girl over the heart above and to the left, a noise very like the clucking of a young chicken, synchronous with the systole. The sound was loud enough to be heard by the bystanders.

In the case of a vine-dresser, an ex-soldier, at 41, there was a hard intermittent sound in the precordial region, not coincident with the systole, loud enough to mask all the normal sounds of the heart, and to be heard at some metres from his person. It began suddenly about a month before the examination. The man thought some living animal had taken up its abode within his chest. The nearest approach to the sound that the auscultator could suggest would be expressed by the lettres *grrouou*, 75 times in a minute, in a low but harsh childish voice.

No change was made by acceleration or suspension of the respiration.

The reporter of these two cases attempted no explanation, saying that such phenomena would have to be classed with so many others of a transient nervous, or anomalous character, which are never explained even by autopsy. (*Dictionnaire Annual 1867, from Jour. de Med. de Brux. par M. Putégnat.*)

Mr. Chairman, when I consented to make remarks upon Prof. Flint's paper, which he was to offer to this Section, I knew perfectly well that little room would be left for addition or subtraction by commentators. This must be my apology for a rather free handling of the subject, instead of adhering closely to the text presented by so eminent an authority.

Dr. J. S. Lynch, of Maryland, referred to the importance of alteration of the aortic sound in Bright's disease. He thought that a large part of the booming character of the first sound was due to the vibration of the aortic walls at each systole of the heart. He could not understand why increase in the blood pressure in the large arteries should not increase the intensity of the aortic sound. Dr. F. had stated

that the intensity of the pulmonary sound was increased by increase of blood pressure in the pulmonary arterial system. Why should not the same result follow increased pressure in the systemic arteries?

Dr. Garland, of Massachusetts, stated that it was often difficult to decide whether a murmur was coincident with, or replaced the cardiac sound. This is important to decide in diagnosis. He spoke of the importance of getting rid of the respiratory movements in trying to determine this point. A murmur will sometimes disappear when the breath is held for a moment. A deceptive murmur is sometimes heard at the base of the heart, to the right or the left of the sternum and up and down its border. It is systolic in time. The peculiarity of this murmur is that it disappears on full inspiration.

Dr. Donaldson thought it a question whether or not the impulse of the heart could produce a sound. Muscular contraction does not produce a sound, or at least not of sufficient force to be heard without very delicate instruments. Experiments have shown that the first sound is produced by the closure of the mitral and tricuspid valves. Where these have been prevented from closing the sound has been absent. In regard to presystolic murmurs, Dr. Leamy, of New York, has claimed with much plausibility that they are not really presystolic, but that they occur at the beginning of the systole.

Dr. Flint in concluding the discussion, said that many of the points advanced were in reference to the mechanism of the sounds and in regard to murmurs. These he had not touched on in his paper, and therefore he waived any consideration of them at this time. His paper was concerned solely with the clinical aspects of the heart sounds. In regard to the Germans having taught the subject in the same manner as he did, he would call attention to the fact that 26 years ago he had pointed out this plan. He could not explain why the blood pressure acted differently in the pulmonic and systemic arteries, but such appears to be the fact.

THE MULTIPLE WEDGE PRINCIPLE IN THE TREATMENT OF ORGANIC STRICTURES OF THE URETHRA.

BY JNO. S. COLEMAN, M.D., AUGUSTA, GA.

Read before the American Surgical Association, Washington, D. C.,
May 2nd, 1884.

It is now nine years since I published, in the *Medical Record* of New York, my application of the multiple wedge principle to the treatment of organic strictures of the urethra.

To quote from that paper: "It ought to be a self-evident proposition, that it is easier to introduce singly the component parts of a wedge, than to introduce it as a whole. Take, for example, a No. 12 conical bougie, even capillary at its point, and attempt to introduce it into a stricture: Where is the point of friction and resistance? Is it not around

the entire circumference of the stricture? Diminish the size of the instrument, and in a direct ratio, you diminish the amount of resistance. After having passed into a stricture one of these whalebone guides, the second has to overcome the friction and resistance of but half the circumference of the stricture, and the line of contact with the other bougie. Now that we have passed these two, we have a groove in front and behind them through which we can readily pass the third and fourth, having now to overcome the resistance of but one-fourth the circumference of the stricture and the two lines of contact with the instruments already in position."

Since that time, I have treated by this method some twenty-five or thirty cases with invariable success. There was not, in any case, marked febrile disturbance; but in some few cases there was sufficient constitutional irritation to cause me to suspend the treatment for a day or two.

It is my habit to give, as a prophylactic, full doses of quinine, say fifteen to twenty grains per day.

I will give in detail one case, as it fully illustrates my method.—Capt. H. D. F. presented himself for treatment of a stricture of twenty years' duration.

His urine was always voided with difficulty, and the act usually consumed from twenty to thirty minutes of his time.

There was marked cystitis, as evidenced by the abundant mucus and the decomposition of his urine. The fetor of his urine was so great as to necessitate the immediate removal of the "pot de chambre." His strictures had been ruptured twice during the year 1866, and once in 1867, with Holt's divulsor.

Since the last operation, he had wholly neglected himself. March 16, 1879, after a prolonged and tedious effort, I succeeded in *worming* through his stricture one of the smallest-sized French filiform bougies, and securely tied it in *situ*. Five days afterwards I succeeded in introducing a second by the side of the first, but the cicatricial tissue was so dense and unyielding, that it was not until the fifteenth day that I could pass the third.

On the twenty-fifth day I readily passed the fourth and fifth bougie.

On the twenty-eighth day I introduced the sixth. At no time was there any hindrance to the passage of the urine.

Feeling assured that now the caliber of the urethra would admit a good-sized instrument, I attempted to remove the bundle of filiforms. In this I was disappointed, for a sufficient amount of concretion had formed to prevent their removal *en masse*. The string binding them together was cut, when they were readily removed, until the last (the first one introduced) which required some little force to withdraw it. Three inches of its distal end had been covered by a *phosphatic* concretion. About one-half the deposit had slipped off the bougie in its withdrawal. (In subsequent cases I have obviated this *contretemps* by removing from time to time those first introduced and replacing them by new instruments).

My patient was now so nervous that he would not permit me to use a sound.

On the twenty-ninth day, retention of urine having

occurred, the patient was chloroformed and a No. 9 steel sound (American scale) readily passed until it reached the prostatic urethra, where it was arrested by the calculous mass. With a little force it easily entered the bladder. To prevent the possibility of another stoppage, to still further cause the *absorption* of the cicatricial material, and for the purpose of irrigation, I now introduced and tied in a No. 16 Nelaton catheter. Twice daily, a solution of salicylic acid and quinine was injected into the bladder, thoroughly washing it out.

On the thirty-eighth day No. 16 was removed, and No. 18 introduced and kept in place four days.

Steel sounds were now passed, from time to time, until the urethra was dilated up to No. 30 of the French scale. The concretions left in the bladder were all extruded within a week. (These specimens, together with the bougie, are here presented).

The patient was instructed to pass, from time to time, a large-sized sound.

It is now five years since Capt. F. was under treatment, and there has not been, so far as I know, a single symptom of a return of his disease. I know that many of my associates will object to the multiple wedge because of its tediousness.

I claim for it safety, certainty, and a greater immunity from a return of the disease, than by any other treatment known to me. Also that it will obviate the necessity for divulsion, internal or external urethrotomy. My reasons for not accepting any of the above operations are: First; that they subject the patient to an unnecessary risk of life. Second; that in internal urethrotomy from behind forwards, it is necessary to dilate the stricture to the caliber of a No. 7 or No. 9 English scale before the instrument can be used. Third; that internal urethrotomy from without inwards is, under favorable circumstances, uncertain. Even with Mr. Teeran's tunnelled urethrotome (which I consider least objectionable), mistakes are liable to occur, *vide* his article in the American reprint of the *London Lancet* for 1874, page 210, wherein he states that one of Dr. Gouley's whalebone guides "was cut in two about its centre, six inches of the whalebone being left behind in the stricture. As the patient experienced no pain from its presence, I determined to leave it in the urethra, in the hope that it would set up a profuse discharge, and so facilitate the treatment. In this expectation I was, however, disappointed, and on December 1, I removed the broken portion of the bougie after its seven days' imprisonment."

One of the gravest and most obstinate of my cases was that of a gentleman who, under the care of another practitioner (one whom Sir Henry Thompson characterizes as a "knowing man at anatomy"), had been subjected to a forced entrance into the bladder. Pyæmia followed as a result of this violence, with the formation of five abscesses; one at the posterior border of the right scapula, and from which was evacuated at least one gill of pus; one beneath the left tensor vagina femoris; one beneath the right vastus internus, and which I believe reached the popliteal space; and one upon each internal malleolus.

The life of this patient trembled in the balance for

weeks, but he finally made a thorough and complete recovery. His stricture was subsequently relieved by the multiple wedge. My friend Dr. H. F. Campbell, who saw this case in consultation with me, said that it was the only case of pyæmia which he had ever known to recover. I concur in the axiom first enunciated by Professor Syme, that "whenever urine passes outwards through a stricture, an instrument ought with care and perseverance to be got in." Also in the dictum of Sir Henry Thompson: "first and foremost, *dilatation—dilatation always—dilatation without exception whenever it will succeed.*" (Italics mine). In corroboration of my position, I beg leave to make the following quotations:

Dr. Frank H. Hamilton, in his "Principles and Practice of Surgery," says of organic stricture: "To the question so often repeated by inexperienced surgeons—What proportion of organic strictures can be successfully treated by gradual dilatation? we answer unhesitatingly, almost every stricture into which the smallest sound or bougie can be introduced. And to the question which naturally follows, are there any strictures, through which urine can pass, which cannot be entered by instruments, we reply, that we have seldom or never met with them, and that such examples must, at least, be exceedingly rare. It is not pretended that all strictures of this class can be entered at once; but only with patience, perseverance, and skill, within a few weeks, or months at most, they will in all probability yield to the instruments, and the bladder will be safely entered.

"It is an error to suppose that a stricture treated by caustic or incision is cured any more thoroughly than when it has been treated by dilatation, or, as it might be more properly called, by absorption. There is no soundness in the theory upon which the claim is attempted to be sustained; and there is no experience to justify the assumption. We have observed the results of all these forcible methods in many cases; and there is the same tendency in all of them to a return of the stricture, unless the dilatation is afterwards maintained by the occasional and regular introduction of instruments. The only objection that can be offered to gradual dilatation, then, is the length of time it may require to complete the cure, as contrasted with forcible dilatation, caustic, incision and perineal section; but, on the other hand, it cannot be denied that, in point of safety, gradual dilatation has greatly the advantage. Death is seldom or never the result of the latter procedure; but from all that we have seen and heard of the other methods, they are followed by a mortality equal to five or seven per cent. Nor does it seem to vary much whether caustic, internal incision, forcible dilatation, or perineal section have been employed. Indeed, some gentlemen of large experience, who favor frequent incisions, admit a mortality of not less than seven per cent., and regard it as a flattering testimony to the excellency of their practice, because in very many surgical operations which are deemed justifiable the mortality is twenty-five or fifty per cent. The fallacy of the argument is too apparent to require exposure. If one is convinced, however, that the condition of the patient demands speedy

relief, or if it should happen that the stricture will not yield to gradual dilatation, the surgeon may resort to some one of the other methods already named, and which we shall now proceed to describe."

Dr. Otis, in his paper on stricture of the male urethra, its radical cure, 1875, closes with the following paragraph: "Strictures of a caliber of less than 16 or 18 of the French scale (7 or 9 of the English), and hence *below the capacity of the dilating urethrotome* as at present constructed, require enlargement by *gradual* dilatation with soft bougies, when this is well borne; if not, by divulsion or the urethrotome of M. Maisonneuve.

After having been brought by any one of these methods above referred to, *up to a capacity permitting the passage of the dilating urethrotome*, complete divulsion of the stricture by means of this instrument may readily be effected." (Italics mine.)

In Dr. Sands' reply to Dr. Otis, on spasmodic stricture of the urethra, he says: "I have seen, in consultation, persons who have suffered from troublesome hæmorrhage, varying in duration from a few days to a month, in consequence of having been cut with the dilating urethrotome—an excellent instrument of its kind, but the use of which has been carried to a dangerous excess. Finally, I have heard of a number of cases in which death has resulted from the employment of the dilating urethrotome. It is hard to obtain access to these fatal cases, which are not usually reported, and which are generally considered a kind of private property. I can state with authority, however, that three fatal cases of operation with the dilating urethrotome have lately happened in our city hospitals, two of which occurred last week in one hospital.

"In two of the cases mentioned, death took place from pyæmia within a week of the operation. In the third case, death occurred from uræmia on the sixteenth day after the operation, which was performed for the division of an anterior stricture so slight as to be detectable only with a bulbous sound, No. 24 French. At the autopsy three deep incisions were found, involving the anterior $3\frac{1}{2}$ inches of the floor of the urethra, the mucous membrane of which, in this situation, was not thickened, and showed no appearance of disease to the eye.

"A tight organic stricture, undivided, was noticeable at the bulbo-membranous junction. This, during life, had been treated by dilatation."

In the American reprint of the London *Lancet*, for 1874, page 404, Mr. Teeran, in his "Description of a Catheter Urethrotome with Conducting Bougie," says: "Then again, most of the urethrotomes are so large at their vesical extremity that they cannot be used, unless the urethra has been previously dilated up to a certain caliber. This remark especially applies to those urethrotomes that divide from behind forwards. For a urethrotome, to be a safe and efficient instrument for the division of tight strictures in the deeper portions of the urethra, it must possess two important qualities: Firstly, its vesical extremity must be so fine that it can be introduced through very tight strictures. It consequently follows that the urethrotome must be one which divides from be-

fore backwards, for, *if the stricture be capacious enough to permit an instrument to pass which cuts from behind forwards, the indication for any operation is doubtful; for, if we have dilated the urethra up to half its natural caliber, why should we not persevere with the treatment which has been so successful, and that, too, in the worst and most troublesome stage of the complaint?* (Italics mine.) What we want is to save time in certain cases, where patients have, for instance, to go to sea suddenly, and where time does not permit of a course of treatment by gradual dilatation."

In the abstract of Guy's Hospital reports in the *American Journal of the Medical Sciences*, for January, 1879, page 178, the following views are quoted from Mr. Cooper Forster: "He has done external urethrotomy only once in the last seven years, and then regretted it afterwards, and he has never performed internal urethrotomy.

"He relies on the hot bath, opium, and gradual dilatation."

M. Despres, in a communication to the Société de Chirurgie, October 16, 1878, on the extraction of prostatic calculus, "did not wish to perform urethrotomy, as he considers this an operation which *renders stricture more fibrous and resisting.*" (Italics mine.)

In the American reprint of the London *Lancet*, for February, 1879, page 71, I find the following emphatic language from Mr. Messenger Bradley upon the subject of internal urethrotomy:

"In boldly criticising it, then, as dangerous and unsatisfactory, I would have you remember that it is criticism of one who has never performed it, and who, I think I may add, never will."

Sir Henry Thompson, in his "Clinical Lectures on Diseases of the Urinary Organs," and, than whom, upon this subject, there is no higher authority, fully sustains me in the position I have assumed. *Vide* page 32 of the above mentioned monograph:

"I will touch lightly on the continuous dilation or the tying in of the instrument. There is a patient up-stairs who is now undergoing it successfully. You have tried, we will suppose, the simple dilatation, and have not made the amount of progress desired, or perhaps the patient's avocations may make it necessary to have a more speedy cure. In either case you may say, if you can give me ten or fourteen days in your room, not necessarily in bed, but on the sofa quietly at home, I can almost certainly bring you from the smallest number up to the highest—that is, by continuous dilatation." As to the length of time required, Sir Henry claims greater potency for the continuous method than I have, as yet, been able to obtain. "In simple dilatation the instrument is simply introduced and withdrawn; in continuous, you tie the instrument in, and allow it to remain for several days. You tie in a small catheter, which, if possible, is to be gum elastic, and so that it just enters the bladder. And you should always take care that it is small enough to pass easily, so that it lies loosely in the canal. Those three conditions being granted, *this is one of the safest and best modes of treating stricture.*" (Italics mine.)

In response to a note of inquiry, my friend, Dr. Eugene Foster, member of the American Public Health Association, and President of the Georgia State Medical Association, kindly furnishes me with the following communication:

AUGUSTA, GA., Nov. 23, 1883.

DEAR DOCTOR:—In reply to your letter of the 22nd, asking my experience in treating strictures of the urethra by your multiple wedge principle, I beg to submit the following answer: I have treated sixteen cases of close organic stricture by your method (several of them of years' standing), and every one of them successful. Your plan of treatment has, in my hands, proven itself all that you claim for it. I am amazed that surgeons generally have not tested its merits, and long since given you credit for your valuable suggestions.

Very truly yours,

(Signed) EUGENE FOSTER.
To Dr. Jno. S. Coleman.

CONCLUSIONS.

In the foregoing paper the following are the principal precepts that have been advocated.

First: That in the treatment of organic strictures of the urethra, urethrotomy whether internal or external, and also the method by divulsion, are attended with serious risk to the patient on account of hæmorrhage, pyæmia and uremia.

Second: That strictures treated by these methods are no less liable to recurrence than those treated by gradual dilatation. Indeed, unless followed by persistent dilatation they are subject to early relapse.

Third: That gradual dilatation of urethral strictures, though of slower progress in the beginning, is almost entirely free from danger, more permanent in its results, and upon the whole the shortest and most perfect method of cure.

Fourth: That in the treatment of tight urethral strictures the *Multiple Wedge Principle* devised by the writer, viz.: That of introducing side by side and one at a time successively a number of filiform bougies, whether applied to the interrupted, or the continuous method, offers to the surgeon the easiest, safest and best method for effecting the solution, or *absorption* of the inodular tissue, and for removing the obstruction.

NOTE.

In the discussion of the above paper, as reported by the *Medical Record* of New York, "Dr. Sayre thought it somewhat strange that the author of this paper claimed to be the originator of the Multiple Wedge System, since, to his personal knowledge, this system had been in use in Bellevue Hospital, New York, for at least twenty years."—To me, it is passing strange that my friend, Prof. J. W. S. Gouley, a member of the staff of Bellevue, and, the author of one of the best monographs on "Diseases of the Urinary Organs," should not have appreciated a system which, according to Dr. Sayre, had then been in use *in the hospital* for eleven years. That he did not do so is manifest from the following language in his letter to me of date Dec. 9th, 1874: "I have

myself wedged in two and sometimes three of these bougies side by side, and have thus rendered otherwise impassible strictures amenable to ordinary dilatation. Three years ago, I had some probe-pointed whalebone bougies made very small (capillary) for the first two inches from the vesical end and thence increasing gradually to Nos. $\frac{1}{2}$, 1, 2, 3 and 4, so that I could accomplish more dilatation with a single bougie at one sitting than I could with two or three ordinary whalebone capillary bougies introduced side by side." (Italics mine.) I claim to have made the Multiple Wedge Principle a system for the treatment of tight, close, otherwise impassible strictures; to have given it a name, and, to have been the first to make it known to the profession.

Whewell says: "Names record discoveries."

SPECIFIC TREATMENT OF DIPHTHERIA AND CROUP.

BY GEO. A. LYNN, M.D., MONONGAHELA CITY, PA.

Read to Section on Practice of Medicine and Materia Medica of American Medical Association, May, 1884.

The efforts of many earnest workers in the medical profession, have of late years been directed toward investigating and seeking to isolate the causes of disease. And the tendency is to ascribe the cause of a class of diseases to the presence in the human body of a contagium, spore, or morbid germ, producing zymosis, with more or less intense disturbance of general nutrition, with or without local lesion of the solids.

As yet none of these have been satisfactorily determined. And while this work is necessary to the advancement of medical science, yet it would be of little avail to the human family to isolate, classify, and describe a morbid element, so long as we have no antidote for it, or means of protecting the human body from its ravages.

Prof. William Pepper, in his address on medicine, delivered before this association at Richmond in 1881, said: "It is clear that if we possessed a perfect antidote for the poison of a zymotic disease, our medicinal treatment would resolve itself into the administration of that antidote in suitable doses and forms, with due regard to the state of the digestive organs.

It seems yet presumptuous to hope that we shall ever possess such antidotes for the acute infectious diseases as we have for syphilis and malaria. But I cannot omit a passing reference to the remarkable results that have recently been observed to follow the use of large doses of bichloride of mercury in diphtheria."

After stating that the subject was brought to his notice, by a paper I read before the Washington County Medical Society, and published in the Transactions of the State Medical Society of Pennsylvania for the year 1879,—he gave a notable example of the efficacy of the treatment in a desperate case of diphtheria under his own observation, in which the result was highly satisfactory. And added, "The

extraordinary tolerance of such large doses of bichloride of mercury, and the rapid and progressive improvement from so desperate a state, makes me regard this as one of the most remarkable cases I have ever witnessed."

The object of this paper is to show the proper method of using the bichloride of mercury as a specific in the treatment of diphtheria. The mere use of a remedy does not necessarily constitute its use as a specific. For instance if one should attempt to control a malarial fever with $\frac{1}{4}$ grain doses of sulph. of quinia given two or three times a day it would most signally fail, and he might say that he had tried the remedy and it had failed in his hands.

So in using the bichloride of mercury as a specific in diphtheria, the dose, time of giving, and stage of the disease, are as important as the remedy itself.

Without entering into a discussion of the pathology of the disease, I may point out what seems to have escaped the notice of most writers on diphtheria, that there are two distinct stages in the disease; one the disease proper which lasts from three to five days, and terminates in the full development of the membrane and the generation in it of a deadly poison, the other, the effects of the absorption of this poison, which is generated in the membrane ONLY, and not in the blood, but when absorbed in sufficient quantity destroys the red corpuscles of the blood. Patients do not die in the first stage of the disease (except in the croupous form) but only from the effects of the poison absorbed from the membrane.

Taking this view of the case to use the bichloride as a specific:

1st. It must be given in the first stage of the disease.

2d. It must be given in large doses, frequently repeated.

The effect of large doses of this remedy, given in the early stage of the disease, is to reduce the temperature, relieve pain in the head, back, and limbs, unlock the secretions, lessen the soreness in the throat, in time, to relieve the nausea and vomiting, restore the appetite; and most of all, it prevents the generation of the poison in the membrane; in mild cases it checks the formation of membrane at once, and causes what is formed to speedily disappear.

Now, as I claim that the greatest virtue of this medicine consists in its preventing the generation of the poison in the membrane, the absolute necessity of giving it early in the disease becomes evident.

It will take physicians a long time to find out the value of this remedy, if they persist in only trying it after everything else has failed, and their patient is in a moribund condition; yet even in such cases, I have known it to prove successful. Prof. Pepper's case, quoted above, if not utterly hopeless, was at least one that very rarely recovers under ordinary treatment.

In using a medicine of so great power, the manner of exhibiting is of some importance. It is best given in solution, so that when excessive nausea is present, the dose may be gradually lessened and the time shortened, giving the stomach a chance to dispose of it, and at the same time keeping up full

treatment. By ordering the druggist to make a solution of the bichloride in alcohol of the strength of gr. j to f. 5j, and dispensing from this, the weighing of a grain and fractional parts of a grain is avoided. Next in importance is a pleasant vehicle in which to give it; this we have in elix. bismuth and pepsin, or elix. of pepsin. Pepsin itself has a good influence in the disease, and is said to have the property of softening the membrane.

In a mild case of diphtheria, I give a child 3 years old $\frac{1}{16}$ of a grain, or in a malignant case $\frac{1}{12}$ of a grain of bichloride of mercury in a teaspoonful of elix. of bismuth and pepsin every 3 hours. To an adult I give from $\frac{1}{12}$ to $\frac{1}{8}$ of a grain every 3 hours.

The manner in which this dose is borne in a bad case of diphtheria is a matter of surprise to a physician using it for the first time. It rarely disturbs the stomach, and soon allays existing nausea. I have never seen it produce ptialism, and it seldom acts on the bowels more than is desirable. I generally order carbonate of magnesia to be given the first night, and after that the action of the bichloride keeps the bowels open. Under this treatment, when commenced early, in an ordinary case the patient will be convalescent by the end of the third day, but in more grave cases, the medicine should be continued to the end of the fifth day—it rarely needs to be given longer.

Thus far, I have been speaking of cases where the treatment has been commenced at the very first appearance of the disease; no tonic or sustaining treatment is needed, and the results are uniformly good; but where the disease has made considerable advancement, and the poison of the membrane is already being absorbed, as may be the case, before the physician is called, the result may not be so satisfactory, and brandy and iron should be added to the treatment.

If we assume that this treatment is no better in results than the general method in vogue, still it has many advantages that strongly recommend it.

There is but one medicine to be given, and there need be no confusion or mistakes. No washes or gargles are needed; no swabs or probangs to be thrust down the throat to strangle and frighten the patient, and make him wish he was dead and at peace; no steaming; no atomizing; none of these—only a teaspoonful of not unpleasant medicine and two or three hours' rest. While I hold that the corrosive chloride of mercury, given in large doses in the very early stages of diphtheria, is a specific, because, when so used, it prevents the generation of the poison in the membrane, and soon arrests its formation, yet membrane is often formed before we are called to the case, or before the remedy has had time to stop the process; and in this case, it may involve the windpipe, or may be primarily formed there, causing diphtheritic croup; and a new danger arises from mechanical obstruction, for which the corrosive chloride gives no relief.

The difficulty of breathing is common to all kinds of croup. It is as great for the time being in simple croup as it is in pseudo-membranous or diphtheritic croup. For this and other reasons it is held by good

authority that the dyspnoea of croup is not due in the main or even in great degree to the mechanical obstruction of membrane in the windpipe, but is rather due to the spasmodic condition of the glottis, and of nervous origin. It is for the relief of this dyspnoea that we resort to tracheotomy, at all times a dangerous operation, and in diphtheritic croup almost hopeless. In any kind of croup the operation, if successful, only enables the patient to breathe. Its effect on the disease is rather to aggravate than otherwise. If we had a remedy that would control and relieve the spasmodic condition of the glottis in croup we would have little need for this operation. And I think we have this in the chloride of gold. A few years ago I was using the chloride of gold, as recommended by Niemeyer in his practice, in some obstinate cases of hysteria, and observed that it had marked effect in nervous affections of the air passages, and was thus led to try it in a bad case of diphtheritic croup, of which I will give a brief history.

In the afternoon I was called to see a child five years of age suffering from a severe attack of diphtheria in advanced stage, it then being the third day of its sickness. Pulse 120, quick, small; temperature 104; respiration 40; tonsils covered with heavy membrane; glands of the neck swollen; tongue heavy furred; breath fetid; nausea and vomiting. From the breathing of the child I apprehended invasion of the larynx.

I ordered one-twelfth of a grain of corrosive chloride of mercury in a teaspoonful of elix. bismuth and pepsin every three hours, with instructions if the child grew worse to send for me.

About 3 o'clock in the morning I was called up, with the information that the child was much worse, and had croup. If this statement was true it made the case nearly hopeless, and I determined to try the effect of the chloride of gold.

Taking with me a solution of the strength of a grain to an ounce of water, I went to see the patient. As reported I found the child much worse,—almost asphyxiated from croup,—lips livid,—cheeks flushed,—dusky red,—and unable to articulate. I ordered twenty drops of the solution of the chloride of gold,—dropped in a glass with a little water,—and given every hour till some relief was obtained. The bichloride of mercury to be continued. In the morning I was agreeably surprised to find the patient very much better,—breathing easy but still having croupous cough. Continued the chloride of gold in the same dose every three hours. The next day the child was still better, asking for food, and quite relieved of croup. The chloride of gold was then withdrawn, continuing the bichloride of mercury.

From this on, the child improved steadily and in three or four days was convalescent.

Since then I have used the chloride of gold in all cases of croup. In simple croup it acts as a specific, and nothing else is needed, and but few doses of this.

The chloride of gold should be given in solution in distilled water. As it is very deliquescent and difficult to weigh, I direct the druggist to dissolve the contents of a 15 grain bottle,—as it comes from

the manufacturer,—in 15 drachms of distilled water, and dispense from this solution.

A caution is necessary in administering,—not to use a spoon,—on account of the strong affinity the preparation has for metals, especially for silver. I direct it dropped in a glass with a little water, and as it is almost tasteless there is no difficulty in taking it. The dose may be from $\frac{1}{50}$ to $\frac{1}{20}$ of a grain every one to three hours.

MEDICAL PROGRESS.

MATERIA MEDICA AND THERAPEUTICS.

ON THE ACTION OF DIGITALINE.—M. Kaufmann has been conducting a series of experiments with this drug in the laboratory of M. Chauveau, the results of which he gives in the *Revue de Médecine* as follows: (He used principally the larger animals, viz.: dog, sheep, ass and horse, for his subjects.)

1. In animals that are in good health, digitaline does not produce diuresis, either when given in large or in small doses.

2. Used hypodermically or administered in powder by the stomach, it produces a diminution in the quantity of urine, and an increase in the quantity of urea.

3. Administered by the stomach in a liquid form and weak dose, it diminishes the secretion of urine and of urea.

4. It does not produce diuresis except in certain dropsies due to affections of the circulation.

GENERAL CONCLUSIONS.

1. Digitaline acts as an energetic local irritant.

2. The general effects are best shown when the solutions are passed into the veins, the trachea or the stomach.

3. The subcutaneous and intra-muscular injections produce a reactive fever.

4. Digitaline produces a slowing of the pulse with a small dose, a slowing followed by an acceleration with a moderate dose, and an acceleration with a strong dose.

5. The inhibition of the heart is due to a bulbar and intra-cardiac excitation of the moderating system, and the acceleration is due to a central and peripheric paralysis of the same system.

6. It raises the intra-cardiac diastolic and systolic pressure, and consequently increases the mechanical work of the heart.

7. It increases the energy of the cardiac contractions and increases the volume of the waves.

8. During the inhibition the cardiac contractions are often associated by twos or threes.

9. During the acceleration the heart beats are regular.

10. In a weak dose, the pulse becomes stronger. In a strong dose, it is strong at first and then becomes weaker.

11. The pulse often takes on the dicrotic or tri-crotic form.

12. Weak doses increase slightly the arterial tension by central peripheric excitation of the vasomotors; stronger doses increase it at first, and then diminish it.

13. It diminishes the rapidity of the blood flow in the arteries.

14. It lowers the temperature of the rectum.

15. It diminishes the quantity of urine secreted by healthy animals.

THE TREATMENT OF THE VERTIGO OF MENIERES DISEASE BY LARGE DOSES OF SULPHATE OF QUINIA. — M. Charcot at a recent clinic at *la Salpêtrière* (*Gazette des Hôpitaux*), presented two cases of this vertigo, with the characteristic shrill sounds, intense hissings in the ears, followed by the sensations of movement in various directions.

The first patient presented these symptoms to a very marked degree on entering the hospital; he had been under the treatment since that time, for a space of three and a half months. First the vertiginous symptoms disappeared, until now there only remains the staggering on walking, or the cerebellar vertigo, which is much more difficult to overcome than the cerebral vertigo. He was treated as follows: For twenty days he was given daily twelve (12) grains of sulphate of Quinia. Then a suspension for ten days. For twenty-seven days the same dose, followed by a suspension of eight days. For twenty-two days the same dose, suspension for nine days. For nineteen days to date of observation the same dose.

The second case was completely relieved. This patient was a woman who was obliged to keep her bed for seven or eight years on account of the severity of these symptoms. She has been for a number of years under this same course of treatment. In 1875 she already showed marked signs of improvement—no longer having habitual vertigo, nor exacerbations, nor disordered movements, nor those sensations of falling which kept her to her bed for so long a period, but at that time she still walked with difficulty, with hesitation and staggering like a drunken person—or like one having been deprived of the use of their legs for a number of years. Now she presents the appearance of one completely cured, walking without the slightest hesitation, and with a firm step. Her health is perfect.

ON THE USE OF CHROMIC ACID FOR CAUTERISATION IN DISEASES OF THE NOSE, PHARYNX AND LARYNX. — Dr. M. Hering has an article on this subject in the *Revue Mensuelle de Laryngologie, d'Otologie et de Rhinologie*, in which he considers:

1. That chromic acid, placed upon metal sounds, is an energetic caustic, but little painful, irritating the mucous membranes but slightly, and used to the best advantage in adenoid tumors, granulations, soft polypi, parenchymatous hyperplasias, etc.

2. A too energetic cauterisation over too extended a surface, may produce either by the absorption of the caustic, or by its introduction into the stomach through the pharynx, symptoms of intoxication, vomiting, etc., accidents which may be prevented by the use of the salts of soda in the solutions. Hering

has never seen any dangerous collapse, or choleraic intestinal catarrh follow these conditions.

3. Infinitesimal quantities are sufficient for cauterisation, an operation which must be performed with care; the surplus of the acid being neutralized, and the cauterisation not repeated until the inflammation has disappeared, and the eschars have dropped off.

4. Chromic acid produces a better effect than any other of the medicaments used at the present day in the treatment of chronic catarrh, with tumefaction and moderate hypertrophy of the turbinated bones; and its best quality is that it produces a rapid cure without causing great pain.

OBSTETRICS AND GYNÆCOLOGY.

PUERPERAL GLOSSITIS. — M. E. Blanc, in *L'Union Médicale*, gives the case of a primipara, 21 years of age, as an example of glossitis evidently associated with pregnancy and the puerperal condition.

The inflammation of the tongue set in at the fifth month of pregnancy. The woman noticed, she said, thick skin forming on the dorsal surface of her tongue, which fell off in a few days, leaving the mucous membrane bare, which soon cracked. Mastication was very painful. Soon new masses of epithelium reformed to disappear in their turn. This same series of phenomena was frequently reproduced, in spite of a variety of topical applications the characters of which were not familiar to the patient. Ptyalism was moderate and there had been no gingivitis.

During the last month of pregnancy this glossitis disappeared spontaneously, to reappear at the time of labor. Blanc saw the tongue covered with a pul-taceous coating, which was thick and white, and which disappeared in two days. Then the mucous membrane became red, glazed as if varnished in the centre, and white on the edges, except at the red points formed by the prominent papillæ. For two days the tongue was completely denuded. Finally the epidermis reformed, and the mucous membrane again became normal about the ninth day.

This condition of the tongue suggested scarlatina, but the patient examined with great care, never had the angina or eruption, and the temperature had always been normal. Moreover, at no time was there any albumen in the urine. It was impossible to find any other cause for the glossitis than pregnancy and the puerperal state, which so often provokes in other cases gingivitis and ptyalism. — *Le Medecin Practicien*.

MEDICINE.

ON THE ATONIC DILATATION OF THE STOMACH. — Prof. Germain Sée and Dr. Albert Mathieu have published in the *Revue de Médecine* the first part of an interesting paper on this subject, with the following résumé:

1. Besides those dilatations of the stomach which are due to a relative or absolute obliteration of the

pylorus, there are others in whom this mechanical cause cannot be considered.

2. In a certain number of these cases, lesions appreciable by the microscope, give a sufficient cause for the exaggerated distension of the organ. (Interstitial cirrhosis of alcoholics, fatty degeneration, etc.)

3. The dilatation of the stomach is produced in a passive manner among feeble individuals, exhausted by a general cachectic condition, in consequence of this weakness, and perhaps, particularly from a want of action of the muscular walls of the abdomen.

4. In the other conditions, there is simply a paralysis of the stomach, which numerous observations assign as the consequence of a general traumatism or an epigastric traumatism.

5. Most frequently simple dilatation of the stomach occurs in individuals who present particularly a condition of general neurosis.

6. It occurs in the course of crises which seem to indicate a successive and alternate intervention of a special state of spasm and atony of the gastro-intestinal motor system.

7. These crises, often painful, sometimes accompanied by diarrhoea, are habitually provoked by an occasional or general cause, such as the emotions, moral shocks; or by a local cause such as excess in, insufficiency or bad quality of food. These crises are in this way the local manifestation of a constitutional spasmodic neurosis (the neurasthenia of certain authors).

8. Constipation and flatulence seem to play an important part in the mechanism of the development of these gastro-intestinal disturbances with a predominant gastric dilatation.

9. Dyspepsia rarely occurs previous to the dilatation but frequently succeeds it. It seems to be characterized by the presence in marked quantity of peptones in the urine.

10. In all cases permanent gastric dilatation does not occur until after alternations of spasmodic action (the cause of the pain and diarrhoea) and of atony (the cause of distension).

THE PATHOLOGY OF THE CERVICAL SYMPATHETIC.—Möbius has given considerable space to this subject in succeeding numbers of the *Berliner Klinische Wochenschrift*, of which an excellent analysis is given by Dr. Francotte, in the *Annales de la Société Médico Chirurgicale de Liège* as follows:

The cervical sympathetic has been the object of numerous experiments of which the principal results are the following:

1. Section of the sympathetic produces dilatation of the vessels in many regions of the head; excitation determines their constriction.

2. Irritation of the sympathetic produces transpiration in different parts of the head.

3. Section of the sympathetic produces a contraction of the palpebral opening and of the pupil, with retraction of the ocular globe; irritation gives the opposite effect.

4. On irritating the cervical sympathetic, there follows a secretion from the parotid and sub-maxillary glands; the saliva is thick and consistent.

5. Irritation of the sympathetic produces cardiac acceleration.

In the healthy man conditions of excitation or paralysis of the cervical sympathetic have often been observed. In the state of excitation there is always, naturally, a connection with the reflex processes, which may have their point of departure at the cerebral cortex. Under the influence of intense emotions, such as fear, the face pales, the brow is covered with sweat, the eyes start out of their sockets, the palpebral openings and the pupils dilate. Passions that are not so strong, as shame and anger, act principally upon the vaso-motor fibres. Painful irritations carry their action particularly to the ocular fibres, and are followed with dilatations of the pupil. The most important cause of the paralytic states of the cervical sympathetic is age. In the old person the pupil and the palpebral opening become contracted, the eyes are sunken and the pupil re-acts but feebly to sensible excitations.

All these phenomena have nothing to do with a direct irritation or a lesion of the cervical sympathetic. The application of a direct irritation, mechanical or electric, to the nerve has often been tried, but the results are open to criticism. It is a question as to whether the results were due to a direct irritation or to a reflex process from irritation of the skin. The interpretation of clinical symptoms is subject to the same error, phenomena may be attributed to a direct lesion of the sympathetic which are due to reflex action. The symptoms observed cannot be attributed to the sympathetic unless a limited alteration of the nerve is noted, or unless there is found in the living subject, a lesion which can act upon the nerve by its seat and nature.

To illustrate this, Möbius details a case which first came under his notice in May, 1882. A student had received a knife wound in the right cervical region, the instrument penetrating to the depth of 12 centimeters (4.7 inches). The wound healed without complications, the patient resumed his studies. He noticed that his right eye became easily fatigued and that it wept after he had read for a time; he noticed at the same time a disagreeable feeling in the right side of the face. On examination, a recent cicatrix was found on a level with the angle of the lower jaw, and extending for a length of three inches, parallel to the anterior border of the sterno-cleido-mastoid with an infiltration cylindrical in form. The right palpebral opening was narrower than the left, the right conjunctiva was slightly injected and more moist than the left. The situation of the eye-ball, its consistency and the appearance of the cornea seemed to be alike on both sides. The right pupil was half the size of the left. Both re-acted equally to light and accommodation. On using the faradic forceps the left pupil dilated a little, the right remained motionless. No notable difference in moisture on either side of the face, but the patient declared that he did not perspire in the neck, nor on the right side of the face, which seemed to be warmer to him. The temperature in the right external auditory meatus was 97.7°, in the left it was 96°. The right ear was redder than the left. The radial pulse was the same on

both sides, 66 per minute. The patient said that it had formerly been 74, and now he frequently felt palpitations, particularly in the afternoon, that were formerly unknown.

Treatment, massage and electrization was ineffectual, but the patient improved somewhat, the palpebral opening enlarged somewhat, the right eye was less easily fatigued, the palpitations diminished and disappeared.

July 18, 1882 (10 weeks about), palpebral opening a little larger, contraction of pupil, injection of conjunctiva, elevation of temperature in auditory canal, redness of ear and absence of perspiration persisted. Pulse, 72-74.

Jan. 15, 1883. Induration in neck almost gone. Right cheek markedly flatter than the left, right eye more sunken in the orbit, seems smaller to the touch, no difference in consistency between the two eyes. Palpebral opening and pupil contracted one-half. Right ear the warmest. Injection of conjunctiva disappeared. No difference to the patient between the temperature and perspiration of the two sides. Palpitations returned. Radial pulse the same on both sides, 88.

Jan. 9, 1884. Right cheek flatter than left, right ear warmer and redder, right eye more sunken, pupil and palpebral opening contracted. Re-action of pupils to light, more sluggish in right, re-action of convergence equal in the two sides, on cutaneous irritation the left pupil dilates a little. Eserine produces a very slight contraction of the right pupil, atropine produces a much greater dilatation in the right than in the left pupil. No atrophy of the tongue, but it is very tremulous. The right side of the neck is very sensible to pressure, the left is much less so. Pressure over the vertebral column at the third and fourth cervical, and fifth and sixth dorsal, as well as in the epigastric region, is painful.

The two hands tremble, particularly the right. The right arm possesses all its motility and its sensibility, it gives a record of 61 with the dynamometer, while the left gives 91. Heart normal, but the patient complains of palpitation. His memory is enfeebled, he is timid and impressionable.

Now for the grouping and utilizing of these symptoms:

1. Contraction of the pupil on the side of the lesion. Never very marked. Re-action to light sluggish, to convergence normal. Reflex dilatation absent.

2. Narrowing of the palpebral opening. This is very marked, and due to paralysis of Müller's muscle.

3. Retraction of the eye-ball. This symptom is less frequently noted than the two preceding, it is only developed later in the course of the affection, and depends, according to Nicati, upon (a) the shrinking of the eye-ball; (b) the atrophy of the fat of the orbit; (c) the paralysis of the muscle of Müller. Besides there is sometimes a softening of the tissues of the eye-ball itself dependent upon deficient nutrition.

4. Vascular symptoms in the head. These are often wanting, but they may escape attention and only manifest themselves under the influence of cold,

of heat, and of the emotions. Most frequently, redness, elevation of temperature and hyperidrosis are observed. But again there may be pallor, coldness, anidrosis, and atrophy of the face. Nicati supposes that these contrary groups of symptoms may correspond to two different phases of the affection.

5. Increase in perspiration. This is attributed to a dilatation of the vessels, but this is contradicted by cases where the part being warmer and redder than healthy portions, does not perspire to a greater extent.

6. Emaciation of the affected part. This is independent of the vascular disturbance, and in this case did not come on for nine months.

7. Modification of the heart's action. This case gives the first record of such a symptom, it causing a slowing of the pulse.

8. Modifications of the salivary secretion. This has never been noted in man. Nor was there any alteration of the thyroid gland. The cerebral symptoms are of doubtful significance. All the nervous symptoms in this case (impressionability, trembling, hyperæsthesia, etc.) are considered by Möbius as reflex, a general neurosis from traumatism.

He considers this case then as an unilateral paralysis of the sympathetic. No cases of double paralysis, or of double irritation of the sympathetic are known. What we know of irritation of the sympathetic is from one case by Eulenburg, and three cases by Seeligmüller. The case of Eulenburg's (pressure on the sympathetic by a goitre) showed dilatation and immobility of the pupil, moderate exophthalmia and paresis of accommodation, coldness of half of the face, and acceleration of the heart's action. In Seeligmüller's cases (traumatic irritation of the sympathetic) there were three times dilatation of the pupil which remained sensitive, and which in two of the cases dilated more upon pressure or electrization of the sympathetic region; in one case dilatation, in two cases contraction, of the palpebral opening; in the one case protrusion of the eye-ball; in one case pallor and coldness of half the face, which in a few days was markedly flattened.

The etiology of affections of the sympathetic embraces most frequently a local cause, as compression by goitre, aneurism of the aorta, carcinoma and other tumors of the cervical and parotid glands, cicatrices, abscesses and various traumatisms. Seeligmüller considers that lesions at the apex of the lungs and the pleura may be communicated to the sympathetics; in fact phthisical patients often present such symptoms.

In concluding his article, Möbius considers migraine, Basedow's disease, facial hemiatrophy, angina pectoris, and progressive muscular atrophy; but does not admit in them any primitive lesion of the sympathetic.

ERRATUM.—The names of John Mills Browne and Albert Leary Gihon, were inadvertently omitted from the list of permanent members from the U. S. Navy and incorrectly included among those from the District of Columbia, pp. 713 and 717, Vol. II, No. 26, JOURNAL OF THE AM. MED. ASSOCIATION.

"OPIUM SMOKING AS A THERAPEUTIC MEANS."—

There are two drugs comprised in our list of therapeutic agents which, however potent for good, are dangerous to human happiness by reason of the very properties which make them boons to mankind. These are opium and alcohol. Each is sure to bring mental, moral, and physical ruin upon its devotee. Each is capable of effecting as complete debasement as did the magic wand of Circe when it transformed Ulysses's companions into swine. The very insidiousness with which these drugs allure their victims increases their danger. Every practitioner of extended experience must be able to recall instances in which the physician's prescriptions proved the foundation of either one or the other fatal habit. We have in mind a young man of brilliant parts who attributed his incurable love of strong drink to the whisky and quinine ordered by the doctor as prophylaxis against malaria. Facts like this are too well authenticated to be denied, and even to mention them may savor of truisms. What then is to be said of the frequency with which the opium habit is contracted under similar circumstances? Often it is the only alternative to an existence rendered otherwise unbearable by excruciating pain. But does this consideration lessen the evils of the habit?

Whether the internal consumption of the narcotic be on the increase, as maintained by some, or not, there is one method of its use which has certainly assumed alarming proportions within a few years—we mean opium smoking. This vice of the East stares us in the face wherever the almond-eyed Chinaman

has made himself a temporary citizen. Would that his vile habit might also depart with him! Our land is particularly open to this seductive vice because of the immigration of the Chinese. Hence, we feel it our duty to protest against the influence likely to be exerted by the article which appears in the *American Journal of the Medical Sciences* for July, 1884. It is entitled "Opium Smoking as a Therapeutic Means," and gives a resumé of the report which Dr. Thudicum made at the Twelfth German Medical Congress of his experience with the narcotic when smoked.

"According to Thudicum, opium smoking gives excellent results in a large number of affections. It rapidly cures a violent case of coryza, causing an almost immediate cessation of cough, and has a very calming effect in phthisical cough. In chronic coryza, also, two or three pipes smoked in the morning will soon bring about a complete cure; and in hay fever it is an excellent remedy. The author has also seen most excellent results in chronic neuralgia and migraine, which had stubbornly resisted large doses of quinine. Long-standing migraine may be cured in three or four months if the patient will persist in the treatment. Certain cases of hyperæsthesia, which sometimes lead to insanity, are also cured by this method.

"Of a large number of cases treated by Thudicum, only one has acquired the habit of opium smoking, so that the method by no means tends to produce the objectionable habit. A person may smoke for a long time and no inconveniences result other than a little digestive trouble. But, on the other hand, care must be taken that the patient smokes a sufficient quantity, as opium, in small doses, is a tonic and stimulant."

We quote the above in order that the reader may judge for himself if the spirit of the article be not calculated to do harm. What is the character of the diseases for which Thudicum recommends the measure? Acute and chronic coryza, phthisical cough, hay fever, chronic neuralgia and migraine, "certain cases of hyperæsthesia that lead to insanity." Are they not the very class of affections, excepting acute and chronic coryza, which, by their very stubbornness, predispose to the acquirement of such a habit? Moreover, it is expressly stated that the means must be often persevered in for several months in order to effect a cure. Finally, are these diseases so unyielding to other remedies as to make opium-smoking the *dernier ressort* and counterbalance the risks run?

Dr. Thudicum has been fortunate in having seen the opium habit confirmed in only one out of the large number of cases in which he has employed it. And it is to be hoped that he will continue to be as

fortunate. But we believe a more extended use of the measure would lead to a different opinion from that uttered by the article in the *Journal*, and that it would hardly endorse, as comparatively harmless, a means so seductively capable of mischief. We sincerely trust it will be long before our American therapeutists countenance this employment of opium. That the habit was formed in one case is proof that it is not devoid of danger, and serves to emphasize the necessity of practitioners of medicine exercising all possible caution in prescribing agents so capable of producing misery.

SIMPLE ABSORBENT COTTON VERSUS THE "ANTI-SEPTIC PAD AND DRESSING."—We have lately been informed by the *British Medical Journal*, June 14, 1884, of an antiseptic pad, manufactured by an American house in London. It is said to have the advantage over the ordinary sponge, in that it absorbs readily without having been previously wetted, and its absorbent power is said to be sixteen times its own weight. It consists of concentric layers of absorbent cotton and cocoa-nut fibre within a covering of gauze. An antiseptic substance is enclosed in a friable capsule in the centre.

Two names of prominent men are associated with this "pad," and yet we feel certain that the reflecting practitioner will consign such a device to the general category of "liver" and other "pads." What special advantage it can afford, except to the manufacturer, over the simple absorbent cotton, we certainly fail to see; and we refer to it only in order to extol the merits for various uses of the last-mentioned article. Absorbent cotton is already widely appreciated by all surgeons. It is constantly used by them, either in its simple form, or medicated as they require it. It can be taken from the packet which the manufacturers furnish us, and at a moment's notice made into a pad of any desired size. Under those circumstances it can be subjected to the physician's sense of touch, so as to realize its quality, whereas, if it is enclosed in a shut sack, any inferior material can be used.

Now, although the surgeon has learned to appreciate the value of absorbent cotton, we are disposed to think that its use is not sufficiently appreciated in the summer complaints of children, in the lying-in room, and certain affections associated with involuntary discharges. Should we be affected with the cholera epidemic now raging in Europe, a judicious use of absorbent cotton for the absorption of discharges may be of incalculable service; and by burning it when it has accomplished its purpose, we

may do more towards confining the disease within reasonable limits than might at first seem possible.

EXCESSIVE MEDICATION.—In the *JOURNAL* for June 21, 1884, we alluded to the strong tendency recently manifested by members of the profession to give large doses, frequently repeated, of active medicines as germicides, prompted by the prevalent germ theories concerning the specific causes of disease. Allusion was made more directly to the use of mercurial preparations in the treatment of diphtheria. Our remarks elicited from Dr. Jno. S. Coleman, of Augusta, Ga., a brief letter stating that he had given to a little girl, aged three years, suffering from a severe attack of diphtheria, 84 doses of the bichloride of mercury, of one-eighth of a grain each, in nine days. The medicine produced neither purging nor ptialism nor any other unpleasant effects; but the patient recovered and is now in good health. Another child in the same family had been attacked with malignant diphtheria a few days earlier, and died without having used the bichloride of mercury as a remedy.

It will be observed that Dr. Coleman's little patient took over ten grains of the corrosive chloride in nine days. But this does not equal in heroism the use of calomel by Dr. I. P. Klingensmith, of Blairsville, Pa., as detailed by him in a short article in the *Medical Record* of New York for July 12, 1884, p. 36. To a child 28 months old, attacked with severe diphtheria, he says: "I at once ordered 20 grains of calomel, which was followed by ten grains every hour until the third day, when, the membrane beginning to separate at the edges, the mercurial was discontinued. During the first three days of the treatment, a total of *seven hundred and twenty* grains of calomel were given." He relates two other cases, one a child aged three and one-half years, to whom he gave at once 20 grains of calomel, and 10 grains subsequently every hour for 15 hours, making 170 grains in less than 24 hours; and the other, a child aged four years, to whom he gave, in similar doses, 130 grains in 12 hours. All three of these children recovered. In commenting on the cases, Dr. K. says: "The calomel purges, but not to excess, causing simply free and copious evacuations of a greenish appearance." And, he adds, "I have never known ptialism to occur in a single case."

In a paper read in the regular meeting of the New York Academy of Medicine, held April 24, and reported in the *Medical News* for July 19, Dr. A. Jacobi decidedly recommends the use of mercurials efficiently in the treatment of pseudo-membranous croup and diphtheria. He gives decided preference to the bi-

chloride and next to the oleate by inunction. But the largest doses he recommends for children from six months to three years old, are from one-fiftieth to one-twentieth of a grain in dilute solution, (1 part to 3000 of water), repeated every one or two hours during the stage of active exudation. And although these doses were generally borne without producing any bad effects, yet he mentions one case, a girl of six or seven years of age, in which three doses of one-twentieth of a grain each, produced griping and frequent bloody stools, making it necessary to reduce the dose to one-fiftieth of a grain. That some patients will tolerate very large doses of mercurials without any bad results, especially when laboring under diphtheria and some other acute general diseases, was demonstrated clinically half a century ago, when scruple, half drachm, and drachm doses of calomel were by no means rare. We have seen many patients who have taken such doses without apparent injury. It was also demonstrated that in most of such cases a large part of the calomel passed through the alimentary canal without absorption, as was probably the case with three-fourths of the 720 grains given by Dr. Klingensmith to his little patient. The bichloride given in dilute solution is much less likely to pass through the bowels without absorption; and though much less likely to induce ptyalism, is more disposed to cause inflammation of the mucous membranes, than calomel.

Our best writers on medical jurisprudence and toxicology adduce cases, in which three grains of the bichloride taken at once, produced intense gastrointestinal inflammation and death. And may it not readily happen that, the same remedy given in smaller doses, but repeated so frequently as to consume more than one grain per day for several days in succession, may accumulate until more than three grains are present in the system at one time? And should such a case happen to result disastrously to the patient, and the practitioner be arraigned for mal-practice, might he not find much difficulty in making a successful defense?

We do not allude to this subject for the purpose of criticising the case related by Dr. Coleman, or those of any other individual member of the profession, for when diphtheria appears in its more severe form, we have no doubt the early and efficient administration of the bichloride of mercury constitutes one of the most reliable means of combating the disease. We desire only to remind the present generation of practitioners that the rapid return to the use of large quantities of active medicines in the treatment of acute diseases under the stimulus of germ theories, is

only repeating, under different names and theories, a practice abundantly tested half a century since. And should the present tendencies continue another decade, so far as mercurials are concerned, ptyalism in all its stages and destructive effects will again become as familiar to the profession and the community as it was to the preceding generations. Yet it must not be inferred that we altogether condemn the use of mercurials in medical practice. So far are we from this, that we have continued their cautious, and we trust judicious, use, in the treatment of a great variety of diseases, through all the changes of medical opinions and fashions of the last forty-five years. But we should dislike to see the extravagances of a past generation again become generally prevalent.

CHOLERA REPORT.—During the last week the epidemic has been steadily increasing in severity, in Marseilles and Toulon. For the twenty-four hours ending yesterday evening, July 20th, at 6 o'clock, the number of fatal cases in Toulon was forty-six, and in Marseilles during the same time, the deaths from cholera numbered fifty-seven, and this notwithstanding over sixty thousand of the citizens of Marseilles had fled from the city by railways and by overland routes as early as the 15th of the month.

Impending famine seems to threaten with added fatality, the panic-stricken people that remain.

Two cases are reported in Transylvania, and again we have the report of two fatal cases in Paris. It is the impression of those best able to judge, that the epidemic is destined to spread throughout Europe. It seems that the Paris Academy of Medicine declines to express to the government its views of the best methods of prevention, and of the treatment of cholera, since its advice as to the holding of the Fete of July 14th had been disregarded, and as regards quarantine measures. Portugal has extended her quarantine to all European shipping. Austria is moving to secure protection to herself as well. At Odessa two weeks quarantine has been established against all shipping from the Mediterranean.

The American Consul at London is instructed to announce that all vessels from Europe must have certified clean bills of health from the American Consuls at the ports from which they sail, or they will not be permitted to enter American ports.

On the 19th inst. President Arthur issued the following timely proclamation:

BY THE PRESIDENT—A PROCLAMATION.—Washington, D. C., July 19.—By the President of the United States of America, a proclamation:

While quarantine regulations are committed to the

several States, the General Government has reposed certain powers in the President, to be used at his discretion in preventing a threatened epidemic. Feeling it my duty, I hereby call upon all persons who, under existing systems in the several States, are intrusted with the execution of quarantine regulations, to be diligent and on the alert, in order to prevent the introduction of the pestilence, which, we all regret to learn, has made its appearance in some of the countries of Europe, between which and the ports of the United States intercourse is direct and frequent. I further advise that the cities and towns of the United States, whether on the coast or on the lines of intercommunication, by sound sanitary regulations and the promotion of cleanliness, be prepared to resist the power of disease and to mitigate its severity, and I further direct the Consuls of the United States in the ports where the pestilence has made or may make its appearance to exercise vigilance in the carrying out of the instructions heretofore given, and in communicating to the Government of the United States any information of value relating to the progress or treatment of the disease.

[SEAL]

CHESTER A. ARTHUR.

By the President:

FREDERICK T. FRELINGHUYSEN,

Secretary of State.

It is hardly necessary to emphasize what we stated last week as to the necessity of thorough sanitation of the cities, thoroughfares and homes of our American people. What we wish now to urge, is, that especially in our great municipalities, where thousands of inhabitants are densely congregated, the work of cleaning and of disinfecting shall *not be delayed*. If cholera comes, let its coming be without invitation. It is no time to renovate cities when the heat of summer is most intense, and to open the cesspools and sewers when the plague is upon us. Vigorous action by those vested with authority will do much to dispel fear, and calm apprehension, and so, in the most effectual manner yet known, disarm the plague of its terror. Let the needed work be done thoroughly and at once.

SOCIETY PROCEEDINGS.

SEWERAGE SYSTEMS AND THE EPURATION OF SEWAGE BY IRRIGATION AND AGRICULTURE.¹

BY HENRY J. BARNES, M.D.

Many of the cities and towns of Massachusetts as well as those throughout the country have in the near future this question to dispose of in a scientific and practical manner. Political economy and the

public health demand attention to this subject already in many communities. An epidemic of typhoid fever in a neighboring town would be a very dangerous menace to the health of the citizens of Boston in consequence of the water supply of the latter being the receptacle for the drainage and dejections of the former. A beautiful lake in the vicinity of Boston is made so filthy by a large sewer discharging into it that twice a public cry of reprobation has been raised against it. The valley of one of our large rivers has been rendered almost uninhabitable by the drainage of a large inland city. It is now said that the citizens of Chicago are much of the time drinking their own sewerage, as a result of taking water from a lake with which their sewerage system connects; and we may add that the city which is not troubled by its system of drainage is the exception and not the rule.

The effects of pollution by sewage of wells, springs, rivers, and ponds used for domestic purposes, are so generally recognized that no attempt is made to collate the many, many calamities which have befallen cities, towns, villages and families through ignorance or indifference as to what disposition is made of the refuse matter of dwellings, and we must also acknowledge that a comprehensive system of disposing of sewage must be inaugurated in the near future, both in towns and by every individual hamlet. The present method of gathering in cesspools or subterranean channels, which discharge in a manner to jeopardize health and comfort of ourselves and neighbors, must be abandoned for a system which shall dispose of and purify the sewage in a practical manner, or we must give up some of our large rivers for sewerage systems, or construct at enormous expense metropolitan systems, both of which have proved unsatisfactory, or failures in Europe.

London's metropolitan system, which discharges in the maritime Thames about twenty-one miles below the city, of which so much was expected, and cited as an example Boston might imitate, has proved far from what was anticipated. The sewage, instead of going to sea, or being diluted to an extent which would render it innocuous, is deposited by the tides above and below the mouth of the sewer in such a quantity as to cause a great cry of indignation from the inhabitants living along the banks of the river, and numerous petitions to parliament asking for relief have been presented.

Torquay and Brighton, draining directly into the sea, have experienced similar results, and their systems are pronounced failures. The once beautiful Bay of Naples is to-day a reeking pool of filth. A recitation of the many examples of pollution of rivers both in Europe and America, and the attendant evils, is unnecessary, but the following list of English cities where the courts have enjoined drainage into rivers, suggests what we may anticipate in this country: Bradbury, Blackburn, Chorley, Doncaster, Harrowgate, Leamington, Merthyr-Tydvil, Rugby, Tunbridge Wells, Warwick, Kendal, Birmingham, Bolton le Moor, Bradford, Coventry, Leeds, Halifax, and Rochdale.

¹ Read before the Section for Clinical Medicine, Pathology, and Hygiene of the Suffolk District Medical Society, April 30, 1884.

In 1870 the Royal Commissioners reporting on the pollution of the Mersey and the Ribble stated "that sewage discharged in running water is not materially changed for many hours by oxidation." This they demonstrated by the following experiment: A volume of filtered sewage from a drain in London was mixed with nine parts of pure water. Analysis of this mixture showed it to contain per 100,000 parts 267 parts of carbonaceous matter and .81 parts of nitrogenous matter. It was exposed each day to light and air, shaken and drawn by small siphons in a manner to cause a fall of over three feet from vessel to vessel. At the end of 96 hours there remained 25 parts of carbonaceous matter and .58 parts of nitrogenous matter, indicating a loss of but 17 parts of carbonaceous matter and .23 parts of nitrogenous matter. At the end of 192 hours it had lost but 25 per cent. of carbonaceous matter and 33 $\frac{1}{3}$ per cent. of nitrogenous matter. This experiment was made in a temperature of 68° F., and was designed to show the change likely to take place in the current of a river running at the rate of one mile per hour, and carrying ten per cent. of sewage. They concluded that there was not a river in England long enough to dispose of a moderate amount of sewage through oxidation.

J. Babut du Mars says, "it has been proved that the waters of rivers do not lose a material amount of azote in a run of over three hundred miles. And the Prussian Government has consequently forbidden the pollution of rivers and seaports by the discharge of the detritus of cities."

The effects of imperfect sewerage systems are forcibly portrayed in a paper printed in the *Boston Medical and Surgical Journal* of February 22, and March 1, 1883. In that paper Dr. Morton Prince collates many epidemics of typhoid fever from this cause. He says, "it is estimated that in this State (Massachusetts) alone there are ten thousand cases of typhoid in each year," and every one knows that a large proportion may be fairly charged to defective drainage. How imperfect sewerage causes this disease was well illustrated at Nahant, Massachusetts, in 1881, and thoroughly reported by Mr. Ernest Bowditch. A paragraph from page 246 of the supplementary report of the State Board of Health 1882-83 would properly introduce the question discussed in this paper, as the successful epuration of sewerage by irrigation and agriculture depends upon where, and to what extent, nature provides in the soil for the elimination of filth. Mr. Bowditch says, after noting the improvement in the sanitary condition of the town the year following the epidemic, "while the conclusions as to soil recovery may be derived from insufficient premises, perhaps calling attention to the subject may lead to the discovery of facts warranting systematic research in this direction that may be of great sanitary value." Dr. Frankland wrote in May, 1881: "There are in nature powerful agents for the destruction of disease. It cannot be doubted: otherwise the human race would long ago have been exterminated. The problem is not entirely solved, but experience appears to demonstrate this action on sewage employed on irrigation, for when

known to be infected by cholera and typhoid fever in England, it has never produced these diseases in the inhabitants living on the sewage farms and consuming the produce."

Many and varied are the systems advocated and methods adopted with the object of disposing of sewage. Surface drainage, cesspools, subterranean drainage, and the pneumatic system of Lienur are employed for collecting and discharging into rivers, ponds, bays, oceans, and on the land are the most common means of distribution. Filtration, precipitation, the employment of chemical agents, irrigation and agriculture are some of the measures adopted for the purpose of epuration.

CESSPOOLS.

Depositing sewage in cesspools is one of the most common as well as antiquated methods. The cesspools are emptied at intervals varying from one week to five or more years. They involve the concentration of fermentescible matter and the consequent generation of gases dangerous to health, beside the vitiation of subsoil water. The soluble organic matter contained in them is capable of very long journeys under ground, with the loss of coloring matter only, as many analyses have proved. Their use should not be tolerated, except the walls are made impervious to liquids, and they should be emptied at short intervals. A writer on the subject says: "The time is not far distant when they will be pronounced a relic of barbarism."

DOWNWARD INTERMITTENT FILTRATION PRACTICED AT KENDAL, ENGLAND.

The population is about 14,000. There are 450 water closets connected with the sewers, which discharge 868,000 gallons per day. A reservoir of deposit was first constructed, which overflowed on a farm of about fifteen acres, with the object of utilization by agriculture. The area of the farm proved insufficient to epurate the sewage completely, and five acres of filter beds were added. These, with the farm, suffice to purify the water. In 1875 the products of one-third of the farm, consisting of cabbages, beets, celery, and rhubarb, sold for \$500. Oats and rye on another third \$375, and on the remaining five acres \$225 worth of hay was raised, making a total of \$1,100 worth of produce from fifteen acres. The application of the sewage cost \$550.

The operation of the same system constructed by I. Bailey Denton, at Abingdon, Great Malvern, and Halstead, England, and at Forfar, Scotland, has proved satisfactory, inasmuch as sufficient matter is eliminated to allow the effluent discharge into neighboring rivers, although it contains a large amount of putrescible matter, as indicated by analyses. It just escapes the ban of the Pollution Act.

THE PNEUMATIC SYSTEM OF LIENUR

is employed at Amsterdam for a limited number of the inhabitants. The sewer-pipes are made of iron, with air-tight joints. An air-pump makes a vacuum.

Closets are opened simultaneously once a day in section after section of the city; the content is drawn to the mouth of the sewer, from which it is carried away in barrels and deposited on the land. Its enormous cost bars its employment where any other system can be used.

UPWARD FILTRATION AT BIRMINGHAM, ENGLAND.

Population about 350,000. Eight thousand water-closets connected with the sewers, which discharged about 14,000,000 gallons per day in the river Tame. An injunction was obtained to prevent the discharge into the river, unless the sewage was first purified. A reservoir of deposit was built, and a system of upward filtration, but complaint of the continued pollution of the river necessitated its abandonment. The city then attempted irrigation and agriculture, but this was also enjoined. Finally, after much delay and litigation, the city bought 120 acres of land, and on the advice of an engineer constructed a new reservoir of deposit, where they treat the sewage with lime. To 13,434,860 gallons is added thirteen tons of lime each day. This clarifies the water to a certain extent by causing a deposit of about 300 tons per day, which is carted out and buried on the land.

It has been an easy matter to separate material in suspension from drain water by filtration, but as this represents only about one seventh part of the value of sewage for fertilizing purposes the process, though simple, has never proved remunerative, and chemists have been employed to suggest agents which would precipitate the soluble matter, which represents six sevenths of the value. Lime has been employed at Tottenham, Blackburn, and Leicester, but the Royal Commissioners report of each a failure, inasmuch as the drain water after being thus treated contains a large amount of putrescible matter.

TREATMENT OF LIME AND CHLORIDE OF IRON AT NORTHAMPTON, ENGLAND.

To 250,000 gallons of sewage is added about 100 quarts of lime and six quarts of chloride of iron, which are thoroughly mixed, and afterwards passed by upward filtration through a layer of calcinated iron eight inches thick. The waters come out without color or odor, and is then allowed to flow into the river. At first there was no complaint, notwithstanding the presence of a large amount of putrescible matter, but later the river became offensive, and the court has enjoined the discharge of such water in it.

THE A. B. C. METHOD OF SILLAR.

A mixture consisting of six hundred parts of alum, twenty-five parts of burned clay, one part of blood, ten parts of salt, nineteen hundred parts of clay, fifteen parts of animal charcoal, five parts of magnesia, twenty parts of wood charcoal, ten parts of manganate of potash, and two parts of calcined magnesia is added to the sewage to be treated in a proportion of about one pound of the mixture to 250 gallons, thoroughly agitated, and then allowed to settle in large reservoirs, which are alternately emptied, and the detritus taken out, dried, and sold as a valuable fertilizer. The residuary water still contains putres-

cible matter, and notably more ammonia than was in the sewage before being treated.

(To be concluded next week.)

STATE MEDICINE.

ILLINOIS STATE BOARD OF HEALTH.

The regular quarterly meeting of the Illinois State Board of Health was held in its rooms in the Capitol building at Springfield on Wednesday, July 2, 1884.

Present, at the afternoon session, Drs. Haskell, McKenzie, Kreider, and Rauch; Dr. Haskell presiding in the absence of the President; and, at the evening session, in addition to the above, Newton Bateman, the President, in the chair.

Dr. George N. Kreider, of Springfield, appointed to succeed Mr. Reen, of Peoria, resigned, was introduced to the members, and took his seat with the Board.

The minutes of the last quarterly meeting, April 17 and 18, were read and approved; after which the regular order of business was suspended, and the Board went into executive session on certain cases of colleges and practitioners under the Medical Practice Act.

During the evening session, the following quarterly report of the Secretary was presented:

QUARTERLY REPORT OF THE SECRETARY, APRIL 1,— JUNE 30, 1884.

During the quarter ended June 30, 1884, there were received in the Secretary's office 604 communications, letters, papers, etc., exclusive of 107 diplomas submitted for verification, and the affidavits and other papers accompanying applications for certificates in 226 cases. There were sent out, during the same period, 827 letters, postals, circulars, etc., and other communications, and the usual quantity of the Board's publications—reports, registers, preventable-disease circulars, epidemic disease blanks, forms of ordinances, etc. Two hundred and forty-two packages were received, and 212 sent out, by express. Seventy-three telegrams received, and 102 sent.

Certificates entitling to practice medicine and surgery, under the Medical-Practice Act, were issued to 170 graduates upon diplomas of colleges which have complied with the requirements of the Board, entitling them to be classed as in good standing, and to 4 upon length of practice in the State. Under the authority conferred upon the Secretary at the last meeting, seventeen applicants for certificates, holding diplomas of colleges which had not fully complied with the Board's requirements, have been notified that they would have to submit to examinations on the branches or subjects omitted by their respective schools. In nine of these cases, the applicants have already been examined and certificates issued; five of these were examined in hygiene only; three in hygiene and general education; and one on all the branches, including general education. Three

declined to appear to be examined, and have left the State, and the remaining five are now awaiting their examination.

Examinations of five midwives have been made, and certificates issued to three of these who passed successfully, and seven to others upon diplomas and licenses, or other recognized credentials.

MEDICAL EDUCATION.

At the annual meetings of the various medical organizations, State and National, which have been held during the past three months, the subject of the preliminary education of medical students has received more than usual attention. Almost unanimously, the individual members of the profession, and these various organizations as units (with one single exception), have pronounced in favor of exacting proof of proper preliminary education before admitting candidates to the lecture classes. There is, practically, no opposition to the movement, the only dissentients now remaining being a few members of college faculties influenced, probably, by a fear of diminished classes. With few exceptions—and these diminishing in number from time to time—the better class of colleges have already adopted this requirement. Every announcement for the session of 1884-85, thus far received, makes this a distinctive feature, but it is to be wished that the colleges would state specifically in their announcements the kind of examinations applicants would be subjected to, or the proof of fitting education required, instead of merely saying, as some of them do, “a preliminary education is required.”

As illustrating the widespread influence of the effort to heighten the standard of professional acquirements, it may be stated that, at a recent meeting of the Nebraska State Medical Society, the qualifications for admission to membership were so amended as to require that applicants must be graduates of colleges which in all respects conform to the standard of minimum requirements of this Board.

In the further interest of medical education, I think it the duty of the Board to exert its influence toward securing legislation for the proper and adequate supply of material for the study of practical anatomy. Colleges in this State have been embarrassed, during the past year or two, in their efforts to properly instruct their students in this most important branch; and the difficulty is increasing. Surgical knowledge and skill cannot be acquired without an intelligent, practical study of anatomy; and in order to secure this, the methods and sources of the supply of material need to be more definitely recognized and regulated by law.

THE PUBLIC HEALTH.

Scarlet fever and small-pox prevailed to some extent during the first half of the quarter, mainly in the southern portion of the State. Except the few cases in Chicago and those in Kendall county, all the small-pox cases occurred in the south half of the State, but scarlet fever was more generally diffused. Both diseases have been of a mild type, with a moderate death rate. As the season advanced there has

been the usual increase in the diseases of hot weather, but not characterized by any noteworthy features.

With regard to further action concerning small-pox, in view of the probability of its epidemic spread from abroad, as shown by its increased prevalence in London and elsewhere, and its frequent introduction into the State from neighboring States, I would suggest that it is desirable to call the attention of sanitary authorities and others to these facts and to the experience of the last few months, which shows that when the disease is introduced into a community where vaccination and re-vaccination were not thoroughly carried out during the recent epidemic, there is still danger of serious trouble. It is also important that county superintendents, school boards and others interested, should have their attention again directed to the fact that the school vaccination order of the board is permanent and continuous, and that its thorough enforcement is expected so as to prevent any accumulation of unprotected or imperfectly protected scholars, from term to term. To this end I think it necessary to again print and distribute copies of the order, with necessary instructions, together with supplies of certificates and blanks for returns to be made through the county superintendent by the first of January next.

Cases of glanders and other infectious diseases among animals continue to be reported to the Board. On the 28th of June Dr. C. N. Cooper, of Batavia, Kane county, reports having a patient under treatment, suffering with glanders, and wishes instructions and advice as to his actions. The amended pleuropneumonia and glanders act has by no means relieved the Board of responsibility in these cases. The public naturally apply to the health authorities in matters pertaining to health, and thus far the State Veterinarian is only reached in a large number of cases through this office. Whether further legislation is necessary on this subject, and what form it should take, are matters which seem to require the consideration of the members.

CHOLERA.

An epidemic spread of Asiatic cholera now seems imminent. What is known as the Damietta outbreak failed to secure a foot-hold in Europe last year, and with the exception of a few isolated cases in Russia and one fatal case at the Smyrna lazaretto—all in July of 1883—it is believed that the disease, from this outbreak was confined to the delta of the Nile. France, it is true, was threatened by the arrival at Havre, of the steamer St. Bernard in June last, with one case on board; but preventive measures were successfully instituted on that occasion and the evil then averted. About the first of May, 1883, the British troop ship, Crocodile, was reported in quarantine at Portsmouth, England, having then had eight cases of cholera on board, six of which proved fatal; but on this occasion also the disease seems to have been confined to the infected vessel. The French have been less successful in their recent precautionary attempts, if it be true, as is now alleged, that the Toulon outbreak was due to a fatal case on board the transport Montebello from China—the infected

clothing of the case not being destroyed. Later advices state that the disease was brought from Egypt in the troop-ship Sarthe. It has already spread to Marseilles and the villages above Toulon, and cases are reported in Italy and elsewhere.

Whether the disease will cross the Atlantic from the east will largely depend, of course, upon the efficiency of the measures employed to confine the contagion to its present localities. Very general activity is manifested by all the European governments and sanitary authorities; and it is to be hoped that they may prove successful, although the dissenting opinions of the English authorities as to quarantine may lead to friction between them and the continental authorities. Meanwhile we are threatened not only from Europe, but from the opposite side of the globe, cholera seeming to be spreading in China, and to have broken out in Japan.

In view of this condition of affairs I have thought it my duty, on behalf of the Board, to urge that the organization of the National Board of Health should be maintained, and have advised to that effect, hoping that it may be possible to still secure the necessary appropriation for this purpose in the Sundry Civil Service bill. Should cholera continue to spread on the Continent it is more than likely to find an entrance into this country, despite the efforts which may be made by local and State authorities to exclude it by quarantine regulations. Want of uniformity, failure to coöperate, commercial considerations, and local conditions, all combine to impair the efficiency of any system of quarantine; and to the extent that these obtain, in the absence of a uniform system, is the danger of failure increased. The remedy, of course, is in the National control and administration of quarantine; and the present emergency furnishes another argument for the continuance of the National Board of Health, with adequate appropriations and increased power and authority.

As to what should be done by us as a Board in the present aspect of affairs, I would say that my own experience and observation lead to the conclusion that it is not judicious to place entire reliance on quarantine measures, no matter how administered, should the disease become epidemic in countries or ports with which this country has close commercial relations. Asiatic cholera, although it may invade places in good sanitary condition, finds its most congenial habitat where filth, in any form, abounds. The best attainable sanitary condition—clean streets and premises; the prompt and proper disposal of organic refuse, night-soil and all forms of sewage; well ventilated habitations with dry, clean basements; a pure and sufficient water-supply; and good individual hygiene, including personal cleanliness, a proper diet, and regular habits of life, these are the best safe-guards against Asiatic cholera, as they are against most diseases. If it should unfortunately appear in a locality whose sanitary condition is good, as thus outlined, there is every reason to anticipate its prompt arrest by well understood measures—thorough isolation of cases, disinfection of discharges, etc. Cholera is pre-eminently a disease to be fought by sanitation.

THE FIFTH ANNUAL REPORT.

Continued delays in the public printing office have still further postponed the publication of the fifth annual report of the Board; but a full force of compositors is now at work upon it, and assurance is given of its speedy completion.

The material for the sixth annual report is in an advanced state of preparation, and, together with the revised official register of physicians and midwives, which is also nearly ready, will be put into the printer's hands as soon as the fifth annual is out of the way.

All of which is respectfully submitted.

JOHN H. RAUCH, Secretary.

At the conclusion of the reading of the Secretary's report, which was accepted and ordered placed on file, the following resolutions were adopted, looking to putting into effect the various suggestions embodied in the report:

Resolved, That the importance of the study of practical anatomy, as a foundation for surgical knowledge and skill, demands that the supply of material for this study be more definitely regulated, and its necessity recognized by law, and that the Illinois State Board of Health respectfully urges the attention of law-makers to these considerations.

Resolved, That the increasing prevalence of small-pox in London and elsewhere, indicating a probable renewal of this epidemic tendency, and its frequent introduction into Illinois from neighboring States within the past few months, make it desirable that vaccinal protection be secured as fully as possible in every portion of the State; and to this end the Secretary is hereby authorized to call the attention of sanitary authorities and others to the subject, and to take the necessary steps to push the further enforcement of the school-vaccination order of the Board, so that all new scholars, and those who have not heretofore fully complied with its provisions, may be properly protected against small-pox before the advent of cold weather.

Resolved, That while epidemic cholera may be excluded from this country by thoroughly-enforced quarantine regulations, yet the best attainable sanitary conditions of every locality in the State should be secured, so that, in the event of Asiatic cholera effecting an entrance notwithstanding quarantine, the disease may be met and fought under the most favorable circumstances; the Secretary is, therefore, hereby authorized to take such action as, in his judgment, will most promptly obtain a thorough sanitary organization of the State, and the adoption and enforcement of the measures necessary to improve its general sanitary condition.

On motion of Dr. Haskell, the Secretary was given discretionary authority to act for the Board in any case of emergency which may arise in the interims between the regular meetings,

During the executive session the cases of a number of colleges, with reference to the requirements of the Board and their standing under the Medical Practice Act; the important features of the office correspondence during the quarter, and the cases of a number

of practitioners, were considered, and the necessary action was taken in a large number of these. The following certificates were also ordered to be revoked :

Certificate No. 913, issued to Peleg W. Blakeley.

Certificate No. 1,103, issued to Fritz Tripple.

Certificate No. 4,027, issued to William Becker.

Certificate No. 3,190, issued to S. Meyer.

After the transaction of sundry routine business, auditing of accounts, etc., which occupied the hours of the morning session, the Board, at 11:30 A. M., adjourned.

BOOK REVIEWS.

CLINICAL LECTURES ON MENTAL DISEASES. By T. P. CLOUSTON, M.D. Edin. F.R.C.P.E., Phys. Supt. Royal Edinburgh Asylum for the Insane. Lecturer on Mental Disease Edinburgh University *etc.*, *etc.* Philadelphia 1884, H. C. Lea's Sons, pp. 550.

To this English work the publishers have added, in the American edition, an abstract of the Statutes of the United States and of the several states and territories relating to the custody of the insane, compiled by Charles F. Folsom, M. D., of Harvard Medical school.

Local laws are so much at variance that perplexing questions are at any time liable to confront the practitioner who has not at hand some such guide to the legal regulations governing these matters.

The body of the work—433 pages in all—is a clinical study of mental diseases of the commoner types based on a wide experience and supplemented by ample statistics.

The subject is treated from so entirely a practical standpoint as to lack something of the fulness of a systematic work, particularly in the line of the history of investigation and the works of other authors.

An effort is made to present the subject attractively by appealing directly to the facts of the pathology and dispensing with elaborate description.

Two hundred and sixty cases from Dr. Clouston's own practice are carefully and critically examined. Seven colored lithographic plates of unusually fine execution add to the value of the book.

Typical cases of insanity rather than rare and unusual forms are for the most part selected for illustrations.

This book is to be commended highly for the clearness of its style and its telling array of cases. The latter are so introduced in the body of the descriptive passages as to make a very attractive combination of didactic and narrative writing. The work will become a standard one on both sides of the Atlantic.

PRACTICAL PATHOLOGY, A MANUAL FOR STUDENTS AND PRACTITIONERS. By G. SIMS WOODHEAD, M.D., F.R.C.P.E. Published by Henry C. Lea's Son & Co., Philadelphia.

This most excellent work does not purport to be a systematic treatise on Pathology, but a guide to the

practical work involved in the study, preparation, and examination of morbid tissues. The more important changes of each organ are described and illustrated, though all the changes which occur could not possibly be considered in the space devoted to the work. The plan of the work follows the various organs and tissues from the postmortem table to the microscope. The first chapter treats of postmortem examinations, the instruments needed and modes of procedure. The second chapter describes very briefly the microscope, for some prior knowledge of this is advised and taken for granted; and gives directions for its use both in examining fresh and prepared tissues. It tells fully how to make injections, how to harden and cut tissues, and discusses clearly the merits of, and describes the methods of using, the common and best staining fluids. The author advises the use of the freezing microtome as enabling the busy student to avoid waste of time in learning to cut sections by hand. Microtomes are now made cheaply, and with a couple of days' practice excellent sections can be made. In regard to staining fluids, picrocarmine is deservedly the favorite with our author. Full details are given of how to make and use the various staining reagents. With the next chapter the consideration of the different organs of the body is begun.

In this short review we cannot consider the remaining chapters. They give clearly a description of the microscopical appearances of the various lesions, and then minute directions for each step in the preparation of the diseased tissue for microscopical examination, and its appearance when examined.

The last chapters discuss the common parasites, both animal and vegetable.

Among the chief and most praiseworthy features of the work are its illustrations. The cuts are not mere diagrams, but accurate drawings. Many of them are original. They are also colored so as to accurately represent the stained tissue.

This book is worthy of much praise, and will without doubt be found of the greatest assistance to those beginning to do practical pathological work. And even those accustomed to the use of the microscope and its accessories will find in it many valuable hints. It is to be hoped that the work will contribute much to make popular, practical pathology.

MEDICAL GERMAN, By Solomon Deutsch, A.M., P.L.D. J. H. Vail & Co., Publishers.

This book is intended to aid the physician in his intercourse with German patients and in reading German medical works. It will be found useful both by those who possess only an elementary knowledge of German and by those more advanced in its study.

The text is separated into two main divisions. The first is practically a glossary of medical terms and words likely to be used in conversation with the sick. The second consists of conversations, questions and answers. There are also German and English indexes which contain nearly 1,400 words.

The utility of such books is undeniable, but they only supplement a study of the grammar and literature. They can not supplant it.

FOREIGN CORRESPONDENCE.

LONDON LETTER.

LONDON, JUNE, 1884.

No doubt many who intend visiting the meeting of the Medical Congress to be held at Copenhagen in August, will avail themselves of the offer of the Ocean Steam Yachting Company to take passengers to the meeting in their steam yacht "Ceylon" for a fare of £30 each person, this to include living on board in port, table wine, and boat service. This arrangement sounds pleasant, and will obviate the discomfort of living in crowded hotels.

Since the suspension of the Contagious Diseases Acts, the various female Lock Hospitals in the towns where the acts were previously enforced seem to have been practically empty, whilst the percentage of venereal diseases amongst the troops seems to be on the increase, in spite of the assertion of those opposed to the working of the Contagious Diseases acts. A deputation of gentlemen opposed to state interference with prostitution have waited on the Home Secretary at the House of Commons and presented a memorial asking the complete and unconditional abandonment of the Acts. The deputation was informed that resolutions of the Justices of Plymouth and from the Grand Jury at Colchester, as well as from the authorities at our other chief military stations, had been received, deploring the increase of immorality and the growth of the want of decorum in public thoroughfares. This the deputation did not agree with, and upon withdrawing undertook to oppose any proposal to re-introduce the acts. It is to be regretted that a small section should be so bent upon doing away with such a useful measure as the acts proved themselves to be during many years.

The cold weather that Western Europe is having has caused many to delay their return from the Mediterranean "littoral." It is to be hoped that those answerable for the "wagon lits" service have taken precautions to have reserve carriages in case of any accident, as at the beginning of the season many invalids, who had paid for proper accommodation on the journey, too often were hurried into ordinary carriages *en route*, through some slight mishap to the saloon in which they started necessitating its being left behind at some stopping-place. Another complaint was that more tickets were issued than compartments were provided.

The Westminster Hospital has one of its wards decorated by the lady members of the Kyrle Society. The walls have been painted representing the four seasons, and have a most cheerful aspect. The Society is to be congratulated upon its success in this case, and if its example is followed in other institutions, it will be a great boon to those who have to spend many weary hours within their walls.

At the annual meeting of the London Anti-Vivisection Society, the committee announced the finan-

cial position of the society to be very flourishing. One of the speakers remarked that science only claimed to have been successful in six or seven points from vivisection, while its advocates did not deny that four or five of these might not have been brought about by other means. Dr. T. G. Vawdrey proposed and carried the following resolution: "That vivisection as a method of scientific investigation is erroneous in theory and misleading in practice, and ought to be prohibited." He said vivisection is erroneous in theory, because it rested on the false assumption that experiments on animals might be applied to the purposes of man. Experimenters could never be certain whether the result of their experiments would be applicable to man, and although they were sometimes, in most cases they were not. At the conclusion of the meeting, a petition embodying the views of the society, for presentation to Parliament, was agreed to.

The general hospital at Peterborough has been destroyed by fire, and the hundred patients who were in it at the time, had a very narrow escape. Within half an hour of the outbreak the building was a mass of flames. One patient was under chloroform undergoing an operation, when the alarm was given.

It is stated that a new edition of the Dictionary of Medicine, edited by Dr. Quain, is going to be brought out. No dictionary of medicine so compendious, and at the same time so authoritative, has yet appeared in any language. Each contributor "volunteered or was invited to write on a subject with which he was specially familiar," and the list of authors is as representative of the best literature of the profession in England, Ireland, and Scotland, as any that could have been framed. If the name of a distinguished authority is missed here and there, this is only the inevitable result of there being other, and sometimes younger men, equally qualified and more conveniently situated for the purpose. A sense of proportion in assigning the space to the several subjects in a vast field of knowledge must be constantly and watchfully observed, along with due consideration for the value of everything that a distinguished contributor would wish to write on his favorite theme. It is given only to a firm hand and a delicate tact to achieve success in such an enterprise, and the measure of Dr. Quain's success must be, on the one hand, the compact form and size of his dictionary, and on the other, the endless variety of the articles and the value of the signatures that they bear.

It may not be generally known that Dr. Laennec, of Paris, in 1819, first made use of a "new method" for exploring the state of the heart and lungs.

Laennec related to one of his friends the story of his discovery. Walking through the court of the Louvre, he observed some children amusing themselves by holding a cylindrical piece of wood to the ear and scratching with a pin on the further end of it, whereby they produced a noise louder than the scratching of a pin produces under ordinary circumstances. Next morning, visiting his patients in the Hospital Necker, he extemporized a hollow cylinder out of a roll of paper, and applied it over the heart of one of his

patients. This was the first stethoscope which he used for some time, afterward superseding it by one made of cedar-wood. He published a treatise on mediate auscultation in 1819. After a short period of indifference, the method began to be warmly taken up, notably by Dr. John Forbes, and Dr. Stokes, of Dublin, and in a thoroughly scientific spirit by Dr. C. I. B. Williams, who published his "Rational Exposition of the Physical signs of the Diseases of the Lungs and Pleura" in 1830, and who still lives to connect the generation of Laennec with the present.

The appointment to the newly instituted University Professorship of Pathology at Cambridge has taken place, the electors being the Vice-Chancellor, Professor Foster, Dr. Gaskell, Dr. Humphrey, Sir I. Paget and Dr. J. B. Sanderson. Their choice fell upon Charles Smart Roy, M.D., who graduated at Edinburgh in 1875. The endowment is £800 a year exclusive of fees. The holder is not allowed to undertake private practice of medicine and surgery.

G. O. M.

DOMESTIC CORRESPONDENCE.

FROM WASHINGTON.

MEDICAL MATTERS BEFORE CONGRESS—MEDICAL INSPECTORS AT FOREIGN CONSULATES—July 2.—The Sundry Civil Appropriation Bill as before the United States Senate, contains the following clause which was adopted. Expenses of State Department. To enable the Secretary of State to appoint from time to time for such period as is absolutely necessary, medical inspectors to be attached to the United States Consulates in countries where yellow fever, cholera or plague exist in epidemic form, \$10,000.

NATIONAL BOARD OF HEALTH.—The same bill contains a clause, which was passed to the effect of striking out the existing clause, "That all laws or parts of laws authorizing the appointment of a National Board of Health be, and the same are hereby repealed;" and to insert, "For pay and expenses of the members of the National Board of Health, \$8,000; and for the investigation of questions affecting the public health, \$10,000."

July 3, in the House of Representatives, the following report from the Committee on Printing (a joint resolution) was passed:

Report from the Committee on Printing on joint resolution (H. Res. 260,) authorizing the printing and binding of additional copies of the reports of the National Board of Health:

The reports for the years 1880, 1881, and 1882, of the National Board of Health contain many valuable papers, covering the results of long-continued and careful investigation in matters affecting the public health. These investigations have been made by men the most eminent in their several lines of study, and it is gratifying to be able to state that the leading sanitarians, both of this country and of Europe, agree in their estimate of the extraordinary value of the service thus rendered by the board. The reports embrace the results of investigations into yellow fever, cholera, diphtheria, the sanitary condition of our summer resorts, the effect produced upon water by its filtration through soils, the sewerage systems of Europe, the flow of sewers, and

the analysis of water, together with reports on many other subjects relating to the public health.

The report on water analysis is regarded by all competent judges to be the most complete and valuable inquiry into the sanitary relations of potable water which has yet been made.

The report on the filtering capacity of soils made under the direction of Professor Raphael Pumpelly, of the Geological Survey, has awakened the liveliest interest among sanitarians all over the world, and has been pronounced to be one of the most important contributions ever made, to our knowledge, of the propagation of epidemic diseases.

The report on the sewerage systems of Europe gives in detail the general systems and their application, together with their cost of construction and maintenance in the principal cities of Europe.

The subject of city and town sanitation is now attracting attention throughout the country, and all reports bearing upon sewerage, water supply, etc., are eagerly sought for.

It is unnecessary to refer in detail to all of the investigations made by the board. The constant demand for them from engineers, health authorities, students in colleges, and sanitarians both in this and foreign countries fully attests their value.

Of the reports published since that for 1879, only the usual number has been printed and the supply of those for 1880 and 1881 has been exhausted, while the report for 1882 has but recently been delivered.

In view of the importance of the subjects treated, and of the great value of the contributions thus made to the general knowledge of sanitary subjects, the board has had its reports stereotyped in order that the cost of reproduction might be reduced to the lowest possible point. The public printer estimates that it will cost \$3,426 to print the number of copies of the reports for the years 1880, 1881, and 1882, called for in the resolution.

Your committee is of the opinion that every effort to improve the sanitary condition of the people should be fostered.

In view, therefore, of the importance of these reports in the addition which they make to our knowledge of sanitary subjects, we recommend the adoption of the resolution.

A. HERR SMITH.

The joint resolution was read, as follows:

Resolved by the Senate and House of Representatives, etc., That the public printer be, and he is hereby authorized to print and bind for use of the National Board of Health 1,000 copies of each of its annual reports, beginning with the year 1880.

MEDICAL AND SURGICAL HISTORY.—July 3.—Mr. Scales from the Committee on Printing introduced the resolution which passed: That the public printer is hereby authorized to print and bind in the usual style 5,000 additional copies of the Medical and Surgical History of the War of the Rebellion, all of which are to be sold to applicants at cost with 10 per cent. added. Provided that not more than one copy of each volume shall be sold to any one person.

MENOXENIA.

EDITOR JOURNAL:

The case of menoxenial anarrhœa recently mentioned in the JOURNAL calls to mind a somewhat similar instance in Pennsylvania, now of some eight years' standing, where the horæal profluvium was effected by expuition instead of by the usual mode. If the source of the catamenial issue was bronchial, it seemed to be very low, and at, or near the pulmonary confluence; evidently the flow was not from the epigastrium. Permanent acyesis ensued, but general health of subject remained good.

Respecting appliances described for better treatment of hepatic ecypsis, it would seem that by the invagination of the drainage-tube within an auliscus

already internally smeared with pus, some of the latter must adhere to the external surface of the drainage-tube, and be subject of (possible) injury by absorption.

The comments of the JOURNAL relative to proposed congressional aid for the permanent abatement of yellow fever are clearly well taken and particularly apropos. If in addition to the appropriation as suggested, some private individual like Vanderbilt would in the fullness of his heart (and purse) seek to immortalize himself by an offer of say one million dollars for fruition, pursuit would be stimulated and success seem more hopeful. After all, however, may not that pyretic scourge be master by aid of heat, filth, and overcrowding? "Frost kills yellow fever," it has been said; but frost will not come at the bidding where the fever may be worst. Let the best, however, be hoped for; man is becoming better and better able to grapple with mighty problems which concern the welfare of mankind.

SPHEN.

Chicago, June, 1884.

REPORT OF A CASE OF FLOATING CARTILAGE IN THE KNEE JOINT.

MECHANICSVILLE, IOWA, June 30, 1884.

M. F. L., 19 years of age, consulted me last September (15) for some "knee joint trouble," giving a history of a fall some six months previous, with injury to the knee, which gave but little trouble at the time. Some three months after the accident, he was suddenly taken with pain and loss of motion, suffering several weeks before relieved. This occurred some three times before he came to consult me. The diagnosis was easily made, as the cartilage could be felt.

I decided to operate for its removal. Æther; antiseptic precautions except spray. Apply bloodless bandage, pressing the cartilage far up the external border of the tendon quadriceps, and securing it in position by very elastic fine rubber tubing. Flexing the knee, I made a valvular incision down upon the upper border of the cartilage.

Opening the sac, the cartilage passed out into the incision and was removed. After all bleeding ceased, sewed up the wound, and dressed it by placing over knee a large sponge wrung out of a carbolic acid solution, and keeping it wet. Placed leg in a well-fitting splint, applying ice to keep the parts at a low temperature.

Dressed the wound in 72 hours. Found wound healed by first intention. No swelling or tenderness about wound or joint. Three days later patient returned home, some 150 miles distant.

That which I wish particularly to call the attention of the profession to, is the use of the rubber bandage to fix the cartilage, and also as a means of excluding all air or blood from the sac.

Immediately upon the escape of the cartilage, the sac receded under the tubing, and it would seem impossible for the air, blood, or contaminating germs to enter. In thus handling these cases, I believe at

least one of the great sources of danger can be avoided.

Yours respectfully,

J. K. MILBOURNE, M.D.

MISCELLANEOUS.

OFFICIAL NOTICE.

ANNUAL DUES from members of the Association—*Five Dollars* per annum—are payable directly to the Treasurer. Such payment entitles them to receive the JOURNAL of the Association for one year.

SUBSCRIPTIONS TO THE JOURNAL from those who are not members should be forwarded to the office of publication, Chicago.

BACK VOLUMES OF THE TRANSACTIONS may be procured, at reduced rates, by addressing the Treasurer.

THE INDEX to the 33 Volumes of Transactions will be forwarded, postpaid, on receipt of *One Dollar* by the Treasurer.

According to a resolution passed May 9, 1884, at the Washington meeting, continuous payment of Annual Dues is required, to retain permanent membership.

RICHARD J. DUNGLISON, M.D.,

Treasurer.

Lock Box 1274, Philadelphia, Pa.

LIST OF OFFICIAL CHANGES IN THE MEDICAL CORPS OF THE NAVY, FOR THE WEEK ENDING JULY 19, 1884.

Medical Director A. L. Gihon, ordered as member of Board of Inspection.

P. A. Surgeon R. C. Persons, ordered to U. S. S. "Saratoga"

P. A. Surgeon C. A. Seigfried, detached from U. S. S. "Saratoga," ordered to Naval Hospital, Brooklyn.

Assistant-Surgeon J. S. Sayre, ordered to U. S. S. "Independence."

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT UNITED STATES ARMY, FROM JULY 12, 1884, TO JULY 18, 1884.

Clements, B. A., Major and Surgeon, also directed to relieve Surgeon J. P. Wright of his duties as Acting Medical Director, Dept. of the Missouri. (Par. 1, S. O. 138, Hdqrs. Dept. of Mo., July 8, 1884.)

McElderry, Henry, Captain and Assistant-Surgeon, from Dept. of the Platte to Dept. of the East. (Par. 12, S. O. 165, A. G. O., July 16, 1884.)

Ewen, Clarence, Captain and Assistant-Surgeon, assigned to duty as Post Surgeon, Fort Sidney, Neb. (Par. 8, S. O. 5*, Hdqrs. Dept. of Platte, July 11, 1884.)

Elbrey, F. W., Captain and Assistant-Surgeon, leave of absence still further extended 6 months on surgeon's certificate of disability. (Par. 6, S. O. 161, A. G. O., July 12, 1884.)

Wakeman, Wm. J., First Lieutenant and Assistant-Surgeon, relieved from duty at Fort D. A. Russell, Wyo., and assigned to duty as Post Surgeon, Fort Washakie, relieving Assistant-Surgeon Norton Strong. (Par. 9, S. O. 58, Hdqrs. Dept. of Platte, July 11, 1884.)

Appointment—Charles B. Ewing, to be Assistant-Surgeon with the rank of First Lieutenant, July 5, 1884, vice Middleton, promoted. (Memo., A. G. O., July 14, 1884.)

No. 5.

ORIGINAL ARTICLES.

ON THE DIAGNOSIS OF TUMORS OF THE ANTERIOR MEDIASTINUM.

BY JAMES C. WILSON, M.D., PHILADELPHIA. LECTURER ON PHYSICAL DIAGNOSIS AT THE JEFFERSON MEDICAL COLLEGE, ETC., ETC.,

Read in the Section on Practice of Medicine and Materia Medica, of Am. Med. Association, May, 1884.

It would be difficult to find in the adult human body a region of less intrinsic interest than that space between spaces known to the anatomists as the Anterior Mediastinum. It is narrow and of little depth; at its superior part a small interval is left between the two layers of pleura which bound it; behind the second piece of the sternum, the pleuræ of opposite sides come into contact and it amounts merely to a thin septum; while lower down it is inclined to the left, and widened out into an angular space of some breadth by the recedence of the margin of the left pleura from the sternum (Quain). It is bounded in front by the triangularis sterni muscle, behind by the pericardium, laterally by the reflected borders of the costal pleuræ, and constitutes a sort of physiological no-man's-land, for it is occupied simply by connective tissue save in its upper part where lies, when it still persists, the shrivelled remnant of the thymus gland.

Six or seven small lymphatic glands lie along the course of the internal mammary vessels. They are for the most part beyond the borders of the mediastinal space, but have nevertheless received the name of anterior mediastinal glands. Nor does this space possess, under ordinary circumstances, the clinical importance that has been ascribed to it "as indicating the position of the anterior margins of the lungs relatively to the heart,"¹ for it is only upon the fullest inspiration that the pulmonary and parietal pleuræ can come into contact at the mediastinal borders, and the relations of the margins of the lungs to the heart must be determined in the living subject by the methods of physical diagnosis rather than by fixed anatomical lines.

But when we consider the Anterior Mediastinum in connection with the pathological processes to which it is liable and in connection with the new growths which occasionally invade it from surrounding structures, it assumes a clinical importance which is not

likely to be over-estimated. On the contrary, systematic writers upon diseases of the chest have too often failed to recognize alike the variety and frequency of the diseases of this region and their importance from a clinical point of view. The students' manuals of Physical Diagnosis, with few exceptions (Gee, Bruen, West,) strangely do not mention them at all. The more pretentious treatises upon Diagnosis and Practice in common use in this country and abroad, for the most part, make the same omission. Important articles have appeared in recent years in the great systems of medicine¹ but much that is valuable is scattered in the journals and reports of societies, and is inaccessible to the majority.

Even those who have most freely contributed to our knowledge of the subject make no formal distinction between the diseases of the anterior and those of the posterior mediastinum. Such a distinction is, I hold, called for by the anatomy of the chest, by the great difference in the contents and relations of these spaces in front of and behind the heart and separated by the middle mediastinum containing the pericardium and its contents, by the different pathological processes to which their contents are respectively liable, by the requirements of accurate diagnosis and finally, by the measures of relief which in certain rare cases become available when, and only when, a differential diagnosis is established.

The morbid conditions to which the anterior mediastinum is liable arrange themselves into two groups; (A) inflammation of the tissues in the cavity, and (B) new growths involving the space and its borders, and are in brief:

A. Purulent Inflammation; B. 1. Cysts; 2. Lipoma; 3. Fibroma; 4. Osteoma; 5. Tubercle; 6. Gumma; 7. Lymphoma; 8. Sarcoma; 9. Carcinoma.

Simple acute inflammation of this region terminating in resolution is practically unrecognizable and unknown.

Of inflammation resulting in the formation of solid exudation, a single case is reported, that of Wildemann. The affection resulted from long continued pressure in the sternal region. The anterior mediastinal space was distended with layers of solid exudation.

On the other hand, abscesses are not uncommon. They may be (a) the result of primary inflammation in consequence of injury and sudden exposure to cold, or (b) secondary purulent collections in con-

¹See Hertz in Ziemann's Encyclopædia, Vol. V.—R. Douglass Powell in Reynold's System of Medicine, Vol. V.—J. Risdon Bennett, in Quain's Dictionary of Medicine.

¹Quain's Anatomy, Seventh English Edition, p. 229.

nection with operations upon the neck, as tracheotomy, or they may be (c) the result of pyæmia.

Cysts in this region are rare. They are mostly of embryonic origin (dermoid) and contain epithelial structures, such as hair, sebaceous and sweat glands, teeth, and occasionally bone, cartilage and other tissues, together with much sebaceous matter. These cysts occasionally develop rapidly and may attain great size.

Lipomata occur as the result of an undue increase of the mediastinal fat, and are associated with excessive accumulation of fat in the pericardium and elsewhere. Such fatty tumors are rare and of very gradual development.

Fibromata and osteomata occur so infrequently that they may be regarded rather as pathological curiosities than as matters of clinical importance. Exostoses springing from the internal surface of the sternum have been met with. They do not attain such size as would permit their recognition during life.

Tubercular deposits in the anterior mediastinal glands are of much less common occurrence than in the bronchial glands. Occasionally observed after death, they do not during the patient's life-time give rise to changes that render a diagnosis of their true nature possible.

Gummata seated upon the anterior and posterior surfaces of the sternum are mentioned by systematic writers upon syphilis.

Lymphoma, sarcoma, and carcinoma constitute by far the greater number of new growths found in the anterior mediastinum. Conclusions as to the relative frequency of these three forms of morbid growth must be based upon the observations of recent years; many of the older cases regarded as forms of cancer being doubtless lymphomata and sarcomata.

Carcinoma probably never occurs as a primary disease of this region. It is met with here even as a secondary growth very seldom, except when it occurs as a secondary deposit from a cancerous breast.

Primary sarcoma is also relatively uncommon. It may originate from a persistent thymus, from the fibrous pericardium, from the periosteum of the sternum, or from the mediastinal connective tissue. Much more commonly sarcomata of this region are secondary to some similar or associated new-growth elsewhere. In a case of my own the primary disease had its seat in the thyroid body.

Lymphoma or lymphadenoma is by far the most frequent form of growth having its origin in the anterior mediastinum.¹ It arises either in the mediastinal glands or in the thymus, and rapidly invades the surrounding tissues, the neighboring glands, the lungs, the heart, and the walls of the vessels which it may even penetrate.

So rapidly and so completely do the malignant growths of this region implicate the surrounding structures that it is, as a rule, quite impossible to determine even after death the starting point of the disease.

The foregoing morbid conditions differ among themselves as to causation, rapidity of development, associated lesions and other important clinical characters; they possess the common traits that they constitute sub-sternal tumors, and that they cannot be recognized as such until they attain sufficient volume to exert pressure upon surrounding organs and modify the physical signs in the region of the chest. It follows that in their incipency diagnosis is impossible. Even when they have attained a considerable size and occasion serious symptoms and coarse modification of the physical signs, their differential diagnosis from analogous conditions of the posterior mediastinal space constitutes one of the most difficult problems of clinical medicine, whilst under certain circumstances their diagnosis from aortic aneurism and pericardial effusion calls for the exercise of the utmost care. Finally, the recognition of the special form of disease with which we have to do is possible only in a small proportion of the cases, and the diagnosis must, in most instances, be of necessity a probable rather than a positive one.

Prominent among the symptoms of mediastinal tumor are, pain, pleuritic in character, commonly superficial, and differing in this respect from the deep-seated, boring pains of aneurism; dyspnoea, increasing day by day and always aggravated by exertion; cough, unproductive or attended by scanty, often frothy expectoration; dysphagia, and a sense of constriction and of oppression in the sternal region. These symptoms, which also occur in other conditions, are characterized by a tendency to paroxysmal intensification altogether peculiar and of itself of diagnostic moment.

Fever is absent, save when it occurs in consequence of some inflammatory complication.

The nutrition is often good, emaciation being present chiefly in those cases in which the œsophagus is pressed upon or implicated. Patients are often well nourished to the last.

When to such symptoms are added certain of the following physical signs, the probability of the existence of mediastinal tumor is correspondingly increased.

Upon Inspection.—Repletion of the veins of the face and neck, lividity of the lips, prominence of the eyeballs, inequality of the pupils, and tumefaction of the tissues of the face, neck, or upper extremities, from serous infiltration; distension of the superficial venous twigs of the upper part of the chest; this often amounts to a mere reddish-blue arborescence, terminating abruptly at or near the sternal borders, but occasionally the superficial veins are enormously enlarged, and form varicose patches of considerable size and prominence; protrusion of the upper sternal region and enlargement of the chest, particularly above the level of the fourth rib, usually asymmetrical; in certain cases an irregular mammilated appearance of the surface, from the protrusion of the tumor through the tissues forming the chest wall; enlargement of the thyroid body, or of the glands at the root of the neck, or in the axillæ, or deformity due to the extension of the tumor upward beyond the sternal notch or the sterno-clavicular articulations;

¹R. D. Powell, M.D., F.R.C.P. Loc. cit., p. 5.

diminished respiratory movements, often asymmetrical.

On Palpation.—The signs of displacement of the apex of the heart, or great enfeeblement of the cardiac impulse, which often is fluttering and irregular; absence of abnormal impulse or thrill.

On Percussion.—Modification of the sternal resonance, with an area of dullness of greater or less extent, involving the upper sternal region, and continuous with the cardiac dullness; dullness in the interscapular region. If there be extensive secondary implication of one or both lungs, the pulmonary resonance will be modified at points distant from the sternum, and collapse of a lung from occlusion of a bronchus, or pleural effusion will yield their known signs.

On Auscultation.—The modifications of the signs relating both to the heart and lungs are of the most varied and diverse character. The sounds of the heart are usually enfeebled, and their rhythm disturbed. In some instances the heart-sounds have been intensified over regions of extra-præcardial dullness. Murmurs may or may not be present, but they never occupy the position, nor do they manifest either the intensity or the rasping character of those of aneurismal origin.

The respiratory murmur is greatly diminished in intensity over the tumor. Stridor is less common than in aneurism, partly because the pressure is apt to be less directly exerted upon the trachea or bronchi, and partly because the common forms of mediastinal growth tend rather to invade than to merely compress at a single point the tubular strictures with which they come into relation. Great enfeeblement of the respiratory murmur over one side may, in the absence of other cause, be of diagnostic value as indicating obstruction of a primary bronchus.

The general diagnosis of mediastinal tumor having been made, the following considerations would favor the probability of its being in the anterior mediastinal space:

(a) Enlargement of the superficial veins of the chest, especially of those below the level of the upper segment of the sternum.

(b) Bulging of the middle portion of the sternum, especially if resonance in the interscapular region remains unimpaired.

(c) Great obscurity of heart-sounds and impulse.

(d) An amount of dysphagia, slight in proportion to the other symptoms of pressure, or the absence of dysphagia altogether.

The differential diagnosis from aneurism of the aorta would be rendered probable if, in addition to the above data, there be

(a) The history or presence of tumors of a malignant nature elsewhere.

(b) An extensive area of dullness without characteristic pulsation, thrill or bruit.

(c) No evidence of disease of the blood-vessels.

(d) No history of excessive or long continued strain, nor of syphilis.

(e) Pain of a stitch-like character, with sense of constriction, rather than the dull, deep-seated, often radiating pains of aneurism.

(f) And the tumor be developed at a relatively early period of life (before the thirtieth year.)

Blood spitting may occur in consequence of the disturbing presence of any form of tumor, or it may be due to the invasion of a bronchus by a malignant growth. It cannot therefore be regarded as of peculiar diagnostic importance.

Tumors of the anterior mediastinum may be distinguished from pericardial effusion by

(a) The irregular outline of the dullness, the greater transverse diameter of which is at a higher level than that of effusion.

(b) Absence of febrile movement.

(c) Absence of the history of the acute or chronic diseases to which pericarditis is commonly secondary (nephritis, rheumatism, etc.)

(d) The progress of the case.

(e) The absence of diverse and irregularly grouped pressure-signs.

The diagnosis of particular forms of tumor of the anterior mediastinum has hitherto led to practical results, only in so far as regards the presence or absence of a sub-sternal abscess or of a cyst amenable to operative measures. Nevertheless Heyfelder¹ had collected in 1863, no less than nineteen cases of resection of the whole or part of the sternum for cancer, abscess and other cause, of which number a single case only succumbed to the operation. In recent years the successful total excision of the sternum for sarcoma, by Koenig,² and successful partial resections of this bone for mediastinal growths³ lend fresh importance to the subject of the diagnosis of these morbid conditions at the earliest possible period of their development.

Mediastinal abscess occupying the anterior space, yields, before its contents have found vent, the following points of difference from other forms of tumor in this locality:

(a) Etiologically, the history of a blow, knock or prolonged pressure upon the sternum; of a wound or stab; of caries or fracture; of an operation in the neighborhood or in the throat or neck; of suppurative disease elsewhere in the thorax, as abscess of the lung or empyema; of severe constitutional disease, or finally, of exposure to intense cold.

(b) Deep-seated, steady, gradually increasing, rather than paroxysmal pain.

(c) The intermittent signs and active movement of irritative fever.

(d) A tendency to "point" and the appearances of a fluctuating, circumscribed, superficial tumor at the sternal border or at some distant position.

In favor of a cyst the following:

(a) Absence of the etiological data of abscess.

(b) Absence of fever.

(c) Evenness of contour.

(d) Absence of positive signs of new-growth, or associated morbid conditions.

³ Küster, *Berliner Klinische Wochenschrift*, No. 20, 1883. pp. 127, 136, 274.

(e) Want of the diversity in the pressure-symptoms met with in the malignant growths.

(f) An obscure sense of fluctuation.

The recognition of a mediastinal fatty tumor would be attended with difficulty, enhanced by the fact that sarcoma of this region may attain considerable size and lead to a fatal issue, without grave impairment of the general nutrition of the body. A woman, aged 60 years, short of stature and enormously fat, died in my ward at the Jefferson Hospital, of sarcoma of the anterior mediastinum, the symptoms of which had lasted almost eighteen months. Kronlein¹ described a congenital lipoma of the anterior mediastinum, in a child aged one year, which found its way through an intercostal space to the surface of the chest, and then rapidly increased in size.

When we come to consider the differentiation of the malignant new-growths which constitute the more common tumors of this region, we find that a probable diagnosis of lymphoma is warranted

(a) When the tumor is primary.

(b) When there are evidences of widespread disease of the lymphatic glands, with or without enlargement of the spleen.

(c) The younger the subject, the greater the probability that the tumor is lymphomatous.

Carcinoma is rendered probable by

(a) The previous or coincident occurrence of cancerous disease in the *mammæ* or elsewhere:

(b) The presence of hard, nodular, immovable masses in the neck:

(c) Relatively slow development of the tumor:

(d) A tendency to rapid emaciation in the absence of evidences of direct pressure upon the *œsophagus*.

(e) The occurrence of cachexia.

(f) The intensity and knife-like character of the pain:

(g) A relatively advanced period of life.

(h) A hereditary predisposition to carcinomatous disease.

If the evidence in favor of the other forms be wanting, the diagnosis of sarcoma may be reached by exclusion. This view would be rendered more probable by

(a) Rapidity of growth;

(b) The history of the amputation of a limb, resection of a joint, or extirpation of any organ for sarcomatous disease.

All these forms of malignant growth are alike liable to be followed by secondary invasion of the lung.

I have purposely omitted, in the foregoing paper, the consideration of many of the multifarious phenomena of pressure and invasion met with in mediastinal tumors. The necessity to be brief has obliged me to simplify the subject by serious omissions. I find a further excuse, also, in the fact that each case must be worked out not so much by fixed rules of procedure, as by careful and painstaking analysis of its symptoms.

LIMITATIONS OF PATHOGNOMONIC SIGNS AND SYMPTOMS.

BY EDWARD G. JANEWAY, M.D., NEW YORK.

Read in the Section on Practice of Medicine and Materia Medica of American Medical Association, May, 1884.

It has been the writer's intention to bring into this short paper, the results of observations extending over some time concerning certain limitations which must be placed upon signs which are considered, when present in certain states, more or less pathognomonic of a definite morbid condition. The word pathognomonic is not used in a strict sense, but somewhat as the word diagnostic. The writer has so frequently witnessed erroneous opinions as to the nature of disease, arising from the reception of some one sign as absolutely determining, that he has been impelled to write this article to impress more forcibly the necessity of studying all the phenomena present in cases of disease. Those diagnoses which are rightly denominated snap, may at times be brilliant, but he who indulges in them frequently, no matter how well informed, will be sure to make mistakes. Diseases do not follow an absolute rule in their manifestations, and he who would have them always square with the written description will obtain but a partial insight into their nature. As the time allotted is brief, I shall only allude to some of the facts of the nature indicated by the title, and not attempt to cover the whole field of medicine. Moreover, I shall restrict it to this consideration as regards signs.

The nervous system allows of fewer claims of pathognomonic signs or symptoms than do most of the other organs. Yet we find that there is a tendency to accept certain states as proving the existence of a given disease. It was not so long since that many were willing to accept the presence of optic neuritis or choped disc conjoined with headache as characteristic of a cerebral tumor; and the change in intelligent medical opinion on this subject shows how the ground shifts with an increasing attention paid to a subject. At present we would accept the optic neuritis as indication of increased intracranial pressure only, not necessarily that this pressure was due to a tumor; moreover we should place the limitation to this consideration by excluding the possibility of Bright's disease, or of this as capable of explaining all the phenomena of a given case. The writer has on a number of occasions found that those who were thoroughly conversant with the examination of the eye, would alter the opinion expressed as to the cause of an optic neuritis as between disease of the kidney, and intra-cranial pressure with the course of the case and the development of symptoms.

Such a symptom or sign can only be accepted with considerable limitation as pathognomonic.

There seems to be a wide discrepancy in this matter, also, as regards the examination of the fundus of the eye, in cases of so-called congestion of the brain. Some have relied upon a certain state of the retinal vessels as proving that the brain was also congested. Yet here, surely, the margin must be very large, for

the writer has met instances in which patients, who, having the same symptoms during their whole course of medical pilgrimage in New York, and at times abroad, also, have been told that they had congestion by some, anæmia by others. Nor would this be alluded to, in this connection, were it not that some have put forth such extravagant statements upon the certainty of distinguishing in this way these opposed states of the cerebral circulation. Volitional tremor is relied upon, also, as discriminative of multiple sclerosis, yet here we have to consider the possibility of metallic poison, especially mercury, or the effects of alcohol, before accepting the tremor as due to this lesion.

Perhaps the most difficult matter which comes to a physician for solution is coma, and if in this state we could meet with some sign of absolute distinction, we might be delivered from much of the uncertainty of diagnosis. There are those who hold that in this state the temperature of the body will furnish a clue as between uræmia and hæmorrhage; but, unfortunately, some claim an elevated temperature, others a normal, as proper to the former condition. The truth is that we find the temperature too variable to become a guide, though a lowering at the outset, with subsequent elevation, points very certainly, if not with absolute positiveness, to hæmorrhage as the cause of the unconscious state. But we meet here a very decided limitation, in that we so often fail to obtain a knowledge of the initial lowering of temperature.

Others have proposed and would rely upon the presence of albumen and casts, one or both, as distinctive between uræmia and hæmorrhage. Alas! only too frequently disease of the kidney co-exists with cerebral hæmorrhage, so that the presence of albumen and casts are not infrequent accompaniments of the latter of these states, and do not help us in deciding as to the cause of the coma. So, too, if we attempt to find some sign which will distinguish between the different causes productive of hemiplegia, it will soon become apparent that there is no infallible guide. The writer has found those signs which are regarded as pathognomonic, as, for instance, between embolism and hæmorrhage, or obliterating endarteritis, liable at times to mislead, unless their application is limited with certain qualifications. For illustration, heart murmurs may exist, and yet, instead of cerebral embolism, hæmorrhage may be the cause of a hemiplegic attack. The reverse is, also, not infrequently true; a heart murmur is absent, and yet cerebral embolism takes place, owing to the obstructing plug having been detached from a thrombus out of the way of the direct blood current, as in the auricle, etc. So, too, an obliterating endarteritis may cause a sudden attack; in such case the already narrowed lumen is probably closed by a rapidly formed coagulum, and that suddenness of onset which is often considered pathognomonic of embolism, or hæmorrhage, be simulated by obstruction. Neither does the method of recovery upon which others would depend always lead us safely through the maze of possibilities naturally inherent in these cases.

Again, rigidity of the neck through tonic spasm of

the cervical muscles, is a valuable sign in cases where a fever or internal inflammation is liable to be confounded with meningitis. It is, however, in no sense pathognomonic, or, rather, admits of considerable limitation.

Beyond those cases where a slight degree of it is present in pneumonia, etc. (of childhood particularly), the writer has found it very markedly present in one case of ventricular hæmorrhage, and in one case of sub-ependymal softening of the lateral ventricle, involving, to a considerable degree, the sensory tracts in their passage toward the occipital lobes. The case was one recently under observation, having severe headache, neuro-retinitis, cerebral irritability, with increasing apathy, to which this symptom became added.

The writer, as others, has been obliged to receive tendon reflexes, or rather their plus and minus changes, with considerable limitations, as indicative of disease. He has found, as others, the normal possibilities too considerable.

Electrical reactions, though much relied on, do not absolutely discriminate the nature of a lesion nor its site; for instance if there is degeneration, reaction present, the lesion may either be situated in the nerves, the anterior nerve roots, in the anterior cornua, or be of uncertain site, as in the case of lead-poisoning. A knowledge of the history and causation is essential to a correct appreciation of a given case.

Illustrations could be given were there time.

In considering pulmonary complaints we find but few signs considered pathognomonic of themselves, but some which in connection with others are regarded as determining.

Thus vocal fremitus is often relied upon as distinguishing between pleural effusion and pneumonic consolidation, where a doubt may have existed, owing to the peculiar combination of signs present. That it has a certain value the writer is prepared to admit, but that it can in no sense be considered as positive, the following brief allusions will illustrate. The writer has met two cases of complete consolidation of the lung with obstruction of the main bronchus by an aneurism in which there was absence of vocal fremitus, etc. Again it is not a very rare event to have vocal fremitus preserved in cases of pleural effusion, nay, even to have it intensified. The writer has frequently noted mistakes made by supposing vocal fremitus preserved, because existing at the upper level of pleural effusions, when absent below. There is perhaps no greater difficulty than is presented by a case of this character in which the bronchial breathing is present to a notable degree. Even the exploratory puncture by the hypodermic syringe-needle has its limitations in these conditions, because it might be possible to have it fail of withdrawing fluid owing to obstruction, leakage, etc., or if withdrawing it, to make sure that it is not because of the existence of a combination of the two diseases. It might be added that the writer has examined some of these cases after death, and became assured that both serous effusion and empyema can, independent of a consolidation, cause increase of vocal fremitus. The limitations then in a

doubtful case become so great that the sign loses a large measure of its force. The limitations of cracked pot percussion note as distinctive of a cavity are so familiar to you all, that it would be a waste of time to repeat them. There may be some, however, who are not familiar with the want of reliance to be placed upon bronchial breathing as discriminating between pneumonia and pleurisy with effusion. It is a very common thing to have bronchial breathing present in cases of pleural effusion, and it follows a certain method and character. It is usually present at the upper limit and has a somewhat sniffing tone, and gives, as compared with the bronchial of consolidation, the idea of coming from a distance. It may, and then usually with these characters, be present over the whole effusion. At times, however, this bronchial breathing is so plain and concentrated that even the best examiners are misled by it into supposing consolidation to exist.

The writer has noticed this mistake more frequently in empyema and in the pleural effusion of inflammatory rheumatism. To make a short digression, the writer will explain one of the causes of this occurring under these circumstances. The patient is hurriedly set up, the physician percusses rapidly, noting dullness or flatness over the lower part of the chest, and then, running his ear over this portion, is struck by finding bronchial breathing, not noting that, as a rule, it is present only at the upper part of the flat or dull region. The vocal resonance is also often misleading, being bronchophonic. Hence in teaching it is wiser to state that bronchial breathing is usually due to consolidation resulting from infiltration, exudation, etc., but at times also to compression of the lung. Limitations too are necessary in considering the importance of the signs considered pathognomonic of a cavity. Probably you are all aware that at times the physical signs of a cavity may exist, and yet the lung be consolidated, or compressed by fluid. The writer has been particularly impressed with this in the examination of certain cases of empyema, serous pleurisy and hydrothorax. Under these circumstances he has heard amphoric breathing, whispering, pectoriloquy, and amphoric percussion note over a space in the lower part of the inter-scapular region, and close to the lower angle of the scapula as a rule, which are extremely deceptive or liable to be so, were the observer not fore-warned by previous experiences. Some of these cases have been followed to the autopsy, others into convalescence, in both series the result showed that these characteristics were simulative of a cavity, not evidences of its existence. No very good explanation could be offered for this deviation from the general rule so far as the writer has been able to study it in the cases which have come under observation. The writer would only draw attention to one point in speaking of the limitation of vocal resonance, because these follow the corresponding breathing states to which allusion has been made, and that is to mention the existence of a normal pectoriloquy of which he has assured himself in a number of cases. His attention was first drawn to it by finding that when describing vocal resonance as heard over normal lung in the usual

terms, and then presenting some one as an example, that the description, and the illustration would not match, but instead, that articulate speech was distinctly audible over the chest.

The pathognomonic importance of râles as indicative of fluids in bronchial tubes or of changes in their calibre, or in the case of the crepitant, of separation of the sticky sides of the air cells and small bronchioles is but little called in question. Yet there are those who believe that pleural conditions cause certain of these phenomena. The writer has met a few cases where a crepitant râle was present in the initiation of a pleurisy. Hence, beyond the usual limitation of this râle, he would add this as of rare occurrence in his experience. Under such circumstances he supposes that the separation of the sticky pleural surfaces so takes place as to produce crepitation instead of grazing or rubbing. There are few cases which would support the view that the subcrepitant râle is of pleural origin; pleural exudation may be met with in some cases where subcrepitation existed during life, but the writer has seen numerous cases in which subcrepitant râles were present during life, and no exudation was present on the pleura post mortem.

Another sign regarded as pathognomonic is the succussion sounds. There can be no question of its origin from the shaking of air and fluid in a hollow space. The writer has, however, obtained it in several other conditions than hydro-pneumothorax, notably so in cases when from catarrhal or other trouble fermentation occurred in the stomach. He has, however, met with but one instance in which such succussion had led to a mistake in diagnosis. In that instance pneumonia existed, and the physician in attendance was led to shake the patient by hearing a metallic bubbling, and observing the splashing sounds came to an erroneous conclusion. The stomach succussion requires the use of a little more force and is not in all instances readily audible over the chest though heard at a distance. The limitation which it would be safer to place in teaching this sound would be that it might arise from other spaces containing air and fluid, as the stomach. It might be added, that the writer has obtained it in a fibrocystic tumor of the uterus whose walls were gangrenous, in an ovarian sac having a communication with the exterior, and in the intestines largely distended; and that though he has attempted to produce it the case of large cavities in the lung he has hitherto not succeeded.

In the study of diseases of the heart, several important limitations are to be placed upon murmurs as pathognomonic. Not infrequently the writer has met persons with weak heart from myocarditis, degeneration, etc., who had been informed, presumably by competent authority, that they had no disease, because of the absence of murmurs, and of evidence of marked enlargement of the heart. And on the other hand, it is supposed that because a murmur is heard over the heart, or in such a position as is natural to valvular disease to occasion it, that said murmur is due to valvular disease. You are all aware of anæmia, and of respiration, as at times the cause of mis-

takes. The writer would draw attention more particularly to the possibility of aneurism, or of arterial degeneration with dilatation causing a murmur in the aorta above the valves, or behind the heart, and transmitted through it so as to simulate aortic or mitral valvular disease. Notwithstanding one is aware of the likelihood of encountering cases of this nature, or that one under consideration may be of this nature, it will be found at times, examining as carefully as possible, extremely difficult to reach a certain decision between such conditions. At least, it has fallen under the writer's observation that such mistakes were made by practiced auscultators, and he has himself been extremely puzzled by some cases of this nature, and come to a right conclusion only after several examinations; and in two which he met some years since, decided upon the wrong condition. One instance in particular impressed him, because of the small amount of trouble. This consisted of a thrombus about $\frac{1}{2}$ inch long, situated on the aorta, about an inch above the valves, taking its origin from an ulcerated atheromatous patch. The ante-mortem diagnosis by a clever physician was aortic valvular disease, obstructive and regurgitant; thus showing that the pre-diastolic aortic murmur caused by the recoil of blood on the valves, or rather, the arterial systolic, may be mistaken for aortic regurgitation. If a digression be allowed for a moment, it may be in order to point out the necessity of keeping in mind, in such cases, that a murmur just before, and, as with the second sound, above the valves, whilst there is no murmur at such time or during ventricular diastole, should raise a suspicion, at least, that the murmur is produced in the aorta, and not at the valves. Such a consideration has been of great service to the writer in establishing the proper site of murmurs.

Another sign which the writer has heard laid down as diagnostic as between an aneurism or a tumor pressing on an artery or in the neighborhood of an artery, is the presence of a double arterial murmur, this being regarded by some as positive evidence of an aneurism. The writer has paid careful attention to this matter, and has found it fail so often that he regards the proposition as utterly untenable. He has had particular occasion to study it in the epigastric region. In four cases of carcinoma of the stomach or lympho-sarcoma in this region, he has found a double murmur present over this area, and in some of these cases, with no pressure exerted by the examiner. The new growth, as the autopsy showed, pressed on the aorta, and at the stenosed portion not only did a murmur occur during cardiac, but also during arterial systole. It should be added, that marked epigastric pulsation was present in all. In a recent case, the writer found such a double murmur due to a partial stenosis of the aorta by connective tissue going over it. The patient had radiating pains from the spine into the anterior crural and lumbar nerves, evincing pressure on these, considerable epigastric pulsation, to which was added this double murmur, particularly audible when the heart was acting strongly. Another limitation is also necessary in the consideration of double arterial murmur, which

has likewise been the cause of difficulty to a number of physicians. This consists in the presence of venous puss in the chest and neighborhood of the aorta. In this latter place it is more deceptive than when found in the neck, though even in that situation, especially in men, the writer has found it mistaken for an aneurismal murmur.

A sign which any physician on first impression would be liable to misinterpret is the severe dyspnœa which at times accompanies Bright's disease. Should one encounter a patient with severe subjective and objective dyspnœa, having at the same time a considerable degree of cyanosis, he would be liable, nay almost certain, to say that such patient had some difficulty with the lungs or air passages primarily or secondary to cardiac trouble. Yet in such condition, independent of the effect of externally received poison, we meet an important limitation, one which is not sufficiently familiar to many physicians. This constitutes the dyspnœa of Bright's disease, or, as some say, the nervous dyspnœa of Bright's disease, asthma of Bright's disease. The writer has met a number of such cases. There is no demonstrable action of the heart; no obstruction in the bronchi; the respiratory murmur is perfect, without the least r  le, and yet the patient feels in himself and seems to others in danger of dying of suffocation. In fact, when severe dyspnœa exists, for which the condition of the heart and lungs offer no explanation, this Bright's dyspnœa should be suspected, and the urine examined for evidences of the disease. The writer would be willing to admit that some cases can be plausibly explained upon the nervous theory, but this explanation will not satisfy the conditions when cyanosis exists. How the nervous system could induce this is a mystery to the writer, considering that the patient may be inspiring and expiring forcibly, and the heart is throwing the blood through the lungs and body (at least there is no proof to the contrary).

The idea which he formed when examining a marked case of this kind, was that by some chemical or other change the red blood globules did not absorb oxygen. All cases in which œdema, hydrothorax, etc., exist, are excluded from this category.

The writer will close the paper by drawing attention to two signs upon which it is necessary to place certain limitations. The first is the presence of albumen in the urine. That this may occur from other causes than Bright's disease is probably familiar to all, and that it can be formed in the urine of apparently healthy individuals has been emphasized of late by several observers. The writer knows of no better illustration than one he met a year ago. The patient, a male, broker, had had severe headaches, and on one occasion, for a time, glycosuria. He had had his urine examined in consequence repeatedly, but albumen had not been detected. Coming to the writer's office one morning in consequence of the headache, he was, as is the custom, asked for a sample of urine. This was found loaded with albumen. The morning and evening urine were requested, but these showed no evidence. A series of experiments were made by the patient, some of which are of sufficient interest to detail. The morning urine would be free, but a cool

sponge bath, reading a book or mental exercise, would instantly cause a marked albumenuria. At no time during six weeks' observation could the writer detect casts, or prove that the kidneys were otherwise affected than to allow from different causes albumen to transude. A re-examination after a lapse of six months showed the same condition.

So also casts, especially the hyaline, may be present in the urine for a long time without thereby proving a serious lesion of the kidneys. It is possible that casts may, under certain conditions, form in normal kidneys.

The writer has recently had occasion to examine the urine of a gentleman who has a considerable number of casts, hyaline or slightly granular, coming only after severe exercise. The urine is normal in quantity, specific gravity, and has not contained albumen. The writer has examined the urine passed at other times of the same day on several occasions with negative results, except the presence of mucus and occasionally mucous casts. Only too frequently we are apt to alarm a patient by the detection of what may be considered a sign of imperfect action, yet not necessarily of confirmed or incurable disease, and to pronounce them afflicted with a malady whose very name is a terror.

These illustrations and remarks will suffice for the end had in view, though the same line of consideration could be continued indefinitely.

THE USE OF ANTISEPTICS IN PUERPERAL CASES.

BY MADISON REECE, M.D., OF ABINGDON, ILL.

[Read before the Military Tract Medical Association.]

During one of the hottest days of the month of July, 1881, I was called to see Mrs. W., near London Mills, in consultation with Dr. Wilson, of that place. I found her in a small bed-room, only large enough for the bed upon which she was lying, with but one window in the room. She had been confined a week previously. Her pulse was 160, her temperature 106°, the tongue dry, abdomen distended to the size of a woman at full term, the secretion of milk suppressed. She was delirious, and an odor filled the room like that of a body far gone in putrefaction.

The husband was informed that there was no probability whatever for the recovery of his wife, every symptom indicating a speedy dissolution. However, I suggested a thorough washing out of the uterus with antiseptics. A half gallon of warm water with two drachms permanganate of potash was prepared. After being placed in a proper position across the bed, a gum catheter of the largest size, with several fenestræ in the lower end, was passed up into the uterus as far as it would go. A common Davidson syringe was attached to it by means of a piece of rubber tubing. The uterus was thoroughly washed out, the injection being continued until the water returning was perfectly free from all odor and clear in color. The discharge from the uterus was of such a pecu-

liarily strong odor, that it was impossible to free the hands from it. It was like that one acquires in the dissection of bodies.

Such a change as took place in this woman's case within an hour, I never before saw in any case. Immediately after this cleansing process the delirium passed off, the temperature fell, the pulse came down—in short, the effect was simply magical. She was given twenty grain doses of the sulphite of soda. The husband was taught how to administer the injections, which were to be given every three hours—one of a solution of permanganate of potash, the other of carbolyzed water, alternately. The patient made a speedy recovery from the severest attack of puerperal septicæmia I have ever seen.

Twelve years before this case, in September, 1869, I was called to see a woman who had had an abortion produced by mechanical means. She had a rapid pulse, high fever, hot skin, unquenchable thirst, irregular chills, an icteric countenance, and a sanious discharge from the uterus that smelled horribly.

A half dozen intra-uterine injections of carbolyzed water thoroughly administered, rescued her from impending death.

Ever since that time I have used this method in all such cases with similar results with a few exceptions. They are to be regarded as similar to surgical fever, the result of decomposing *débris* in the uterus, which is absorbed from the uterine surface, and which Sir James Simpson has aptly compared to the flap of an amputated thigh, with its raw and bleeding surfaces, and patulous vessels ready to absorb decomposing fluids with which they may lie in contact.

The following long-continued case illustrates, in another way, the value of these intra-uterine injections. The last day of January, saw Mrs. M. A., aged 24, living near Hermon, a strong and vigorous woman. She had been confined 24 hours previously. The child was dead when delivered, and was so much decomposed that portions of the skin slipped from the body when handled. She had had a chill and profuse flooding a few hours before I saw her. The pulse was 140, the temperature 105°, skin hot, tongue dry, and abdomen tympanitic and distended to the size it was before her confinement.

The uterus was immediately washed out with carbolyzed water, giving great relief to the patient. The injections were kept up every three hours for a week, with the effect of reducing the temperature after every injection. Quinine was also freely administered. Thinking, perhaps, that the septic matter was sufficiently removed from the uterus, the injections were discontinued. Within 24 hours a severe chill, followed by a high temperature, announced the absorption of more septic material. The intra-uterine injections were again resorted to, with the same results, diminishing of temperature, and lowering of the pulse. At the end of a week, as there seemed to be so much improvement, they were once more discontinued. Again, in a short time, there was a chill and return of former symptoms. Again we returned to the use of the intra-uterine injections, and kept them up until every vestige of fever had disappeared from the case for several days.

In this case there was no bad odor from the discharges, as in the former cases, and the effect of the injections in arresting the poison of the septic matter was prompt and striking.

Should antiseptics be used in every puerperal case? I believe so, especially as antisepsis has come to be considered as the use of every means of cleanliness, and the prevention of infectious or contagious matters. And just here let me record it as my fixed belief, that thousands of women have come to their deaths, from the dirt and other matters under the finger nails of their attendants. That dirt, the nest of infectious particles scraped from the body of himself, or possibly bathed in the infectious fluids of another person, is conveyed by means of the touch to the abraded surfaces in the puerperal patient, and she becomes inoculated with the virus that causes her death. I believe that any one suffering from a chronic skin disease, or who is afflicted with a chronic ulcer of any kind, should not attend upon puerperal patients, no more than he who is attending patients with scarlatina or erysipelas. In fact it is my deliberate judgment, that puerperal women should not be attended by the general practitioner at all, and for one I will gladly welcome the day, when I can turn over all such patients to well educated and thoroughly trained lady physicians who will make that their special calling.

Begging pardon for this digression I would say in conclusion that within twenty-four hours after confinement, the use of vaginal injections of carbolized water, affords the greatest comfort to the patient, bathing and soothing the neck of the uterus where there may be abrasions or lacerations, and cleansing and purifying the parts. If the discharges become foul in odor, and there is a marked rise in the temperature, then the injections should be *intra-uterine*. One precaution should be borne in mind, in prescribing vaginal injections, and that is to have the hole in the end of the pipe or syringe closed. I have in several cases seen a severe and dangerous uterine colic, caused by the injection passing into the uterus through the patulous and open os. In the rubber syringes that are sold for female use, I often prepare the pipe for such purposes by closing the central hole in the end, and enlarging the others in such a way that a backward current is given to the injection.

IMPORTANCE OF DIAGNOSIS IN OPHTHALMOLOGY.

BY E. WILLIAMS, M.D., CINCINNATI, O.

Read in Section on Ophthalmology, Otology, etc., American Medical Association, May, 1884.

If a man were seen firing in the air expecting ducks to fall without looking if any are flying over, he would be brought to court on a quest of lunacy. Why should shotgun practice in the medical profession, similarly aimless, be less criminal evidence of a fool? Rifle

practice in the healing art requires intelligence and skill. No surer proof of a quack can be asked than a prescription containing a great variety of romantic remedies. Quacks and nostrum venders can kill just as well at long range, and with a shotgun, as with an honest, scientific weapon. The honest, educated physician insists on a personal examination before risking an opinion or prescription. Diagnosis demands knowledge, to which there is no royal road.

The prime importance of intelligent diagnosis need not be argued. Narrow notions of specialties in medicine are a great professional misfortune. How often do expectant students propose to study the eye exclusively, without the labor of a regular course of study and a degree? The only antidote to this nonsense is to insist on a good preliminary education, and a thorough study of medicine, through three to five years. If *then* a specialty is chosen, the choice will be discriminating. In that way only can a foundation be laid in solid rock for a special structure.

The eye is the most exquisite part of the body, and more closely linked with the healthy flow of function in the organism than any other organ. No violinist, however gifted, can become preëminent except he begin the manual training in early years. Shall less be demanded of one who is to play upon the living harp of a thousand strings, with its mixed melody of earthly and heavenly vibrations? Light, nimble and delicate manipulations are eminently required in an oculist. These can only be achieved by handy hands, early, long, and faithfully trained.

But without intelligent diagnosis, even these accomplishments go for nothing. Thorough familiarity with optics, including mathematics, is demanded if anything but mediocrity is expected. No department of ophthalmology is of more practical importance than the anomalies of refraction and accommodation. To a thorough, clear diagnosis in these, the physician must be familiar with physiological optics. The flippant way that practitioners talk about "taking up a specialty," were it not for the tragical consequences, would be simply ludicrous.

The mercenary estimate placed by the public on the faithful army of Esculapius, is due largely to failures of diagnosis and their consequences. With few exceptions, the world don't know the difference between a decent physician and professional robbers. They call them all doctors together. The only way out of this "Slough of Despond" is for all educated, decent medical gentlemen to pool their issues against the bloody and thievish-fingered quacks of all colors and persuasions.

All honor to the American Medical Association for the lofty and only safe ground of its Code of Ethics! No one who lives up to its letter and spirit can ever fall into the dirty ways of irregulars and tradesmen in our noble profession. It is the mean, mercenary spirit that eats out all bowels of mercy and scruples of conscience in a medical man. Broad intelligence and thorough honesty are the qualifications of a true physician. I state a fact, that there are too many medical colleges in this country. It is too easy for the ignorant and unscrupulous to get into the motley ranks of our profession. According to

the *Record*, there are 14 chartered medical schools in the State of New York, graduating annually eleven or twelve hundred students. Some of these many mills must be small, and can grind out from the screenings of the others, dangerous and disgraceful doctors, who, as blacksmiths, would be safe members of society. What is true of New York applies equally to other States.

Reform of these crying evils is timidly seen in the general encouragement to lengthened terms of study, and more thorough preliminary education. But the progress is slow, and too closely watched by jealous and selfish eyes. So-called measures of reform are too often but tricks of the trade. I only speak of these evils, as they bear upon diagnosis and reputable practice, without attempting to suggest remedies. Fewer graduates, of a higher order, are what we need. No advanced step can eliminate *all* quackery, but it will leave behind much driftwood which gives force to the impression that medicine is a trade. Scientific accuracy of diagnosis, and intelligent practice, can best come through thoroughness of study, by educated young men. Correct diagnosis, so important in everything, is peculiarly demanded in ophthalmology. Recent studies of the anatomy, offices and diseases of the nervous system, have thrown a flood of light on some of the most obscure troubles of vision. Language read in the eye is often eloquent in differential diagnosis of diseases elsewhere. The oculist cannot afford to be ignorant of the influence of other diseased organs on the eye. Neither can the practitioner in medicine, surgery or obstetrics, longer get on, without serious knowledge of the settled facts and principles of ophthalmology. Broader investigations and higher knowledge come into demand, just as special studies extend the area of our territorial possessions. Territories belonging to the different branches overlap, and each must understand enough to see mutual relations and diagnostic bearings. A surgeon who cannot tell cataract from glaucoma, or strabismus from deviations following paralysis, will make unpardonable blunders. A cataract operation, where no capacity to see exists, is inexcusably stupid. Every one knows the mutual dependencies of internal pathology and many diseases of the eye. Certain general states, as syphilis, scrofula, anæmia, give rise to the most troublesome eye diseases. Depraved blood, the pabulum of all the bodily organs, is the explanation of many problems in the *ars medendi*. I need only refer to retinitis in albumenuria, diabetic cataract, intraocular hæmorrhages, toxic amblyopia, and all sorts of specific manifestations in the eye. How often does spontaneous extravasation of blood under the conjunctiva oculi tell the skilled physician of the danger of apoplexy? This, in itself trifling symptom, in advanced years portends grave danger, and ought to be heeded. Conscience cannot be satisfied with prescribing eye water in such cases.

But what has ophthalmology to do with obstetrics? To say nothing of the immediate and remote connections of derangements of menstruation, and other uterine diseases, with serious troubles of vision, I instance pregnancy. The occurrence of albumenuria,

in the period of gestation, involves the greatest danger. Puerperal convulsions, the horror of obstetricians, are imminent under such circumstances. Failure of sight from albumenuric retinitis is often the first warning. The retinal changes are so characteristic, that the diagnosis of kidney disease can often be made from them alone. The fatal effects of ophthalmia neonatorum on the eyes of infants, can be seen in all our blind asylums. Nearly half the inmates owe their condition to this disease. Let alone, or treated with old women's remedies, especially if aided by poultices, many of them will lose one or both eyes. This disease can nearly always be prevented. For twenty or more years, I have exhorted my students to wash the eyes thoroughly as soon as the infant is born. The eyes should be opened and clean tepid water made to flow through them, so as to remove all possible poison. This fatal disease is due to inoculation with the mother's secretions. If active gonorrhœa be present, or suspicious discharges, a few drops of a weak solution of nitrate of silver should follow the washing. One to two grains to the ounce is strong enough. This prompt attention will nearly always anticipate the disease. A large number of recent observations in lying-in hospitals, and in private practice, prove this beyond question. Even where the purulent disease has set in, prompt and proper treatment will save the eyes from damage.

The intimate connection of certain eye symptoms with disease of the brain and spinal cord, has long been known. The numerous books and monographs recently published on that subject are nearly all by ophthalmologists. They treat mostly of such phenomena about the eyes and vision, as help to locate the seat and nature of the lesion in the brain. These studies have led to remarkable results in cerebral physiology and pathology. A new field of vast reach has been opened to the study of cerebral localization. The wonderful results of these special inquiries are but beginning to show. A work in German, published in this year, by an oculist of Hamburg, brings together all the known clinical facts about the eye in hemiopia. He desires to show their importance in locating the seat of the brain lesion, be it in the optic tracts or in the visual centres in the cortex.

In the study of locomotor ataxia, much interest has always attached to the two most frequent manifestations in the eye, optic atrophy and extreme contraction of the pupil. The former results, usually, in total destruction of the sight. The latter, when present, persists when all perception of light is extinct. I recall one patient, totally blind for years, where the very small pupils are still the same. In such cases, even when vision is little, if at all impaired, the pupils do not respond to changes of light. But the moment the patient tries to focus for print, the pupils contract, dilating a little when accommodative tension relaxes. The small pupil, when present, indicates the cilio-spinal region of the chord as the chief seat of sclerosis.

Double optic neuritis, generally, means a serious lesion of the brain. If attended by paroxysms of severe head-ache, and sudden causeless vomiting, the

diagnosis of tumor of the brain is next to certain. The most striking symptoms of optic neuritis, are often seen where the sight is little impaired. Double optic neuritis often persists for years, before total blindness, or death, occurs. I recall a poor patient woman, whom I treated five and six years. At last she succumbed to acute pneumonia, never having become entirely blind. Other complications must be looked to in order to form a rational opinion of the seat of disease. But the diagnosis is not always certain, till explained by the autopsy. I have now under treatment a young lady of 18 years, with the most marked symptoms of double optic neuritis I ever saw. She is in fair health and at school. She has had imperfect sight since her third year, and says the defect of vision has been about the same for many years. Her father became blind at 25 and remained so till his death a few years ago. Cause of his trouble not known. The sight of the patient is 0.1 in both eyes. The mother and sister have perfect vision. She can read no $3\frac{1}{2}$ at 6 inches and keep up with her classes. No glasses help her at all. The optic papillæ are enormously swollen and present a woolly appearance. The veins, large and tortuous are less obscured by the opaque tissues, than the arteries. There are no retinal hæmorrhages. The periphery of the fundus oculi is much clearer than its central portion. Our first examination was Feb. 26, 1884. At the second, four weeks later, there was no change. There was absolutely no other symptom to explain this peculiar state of things, than the facts stated. It is quite probable that blindness from optic atrophy will be the final issue.

As showing the frequent dependence of serious ailments of sight upon uterine diseases, I refer to the following: A married lady 27 years old had a large patch of central choroiditis, with corresponding scotoma, in the left eye. The atrophied portion is white, and bounded by a ring of pigment, and she can only count fingers at 8 inches. In the right eye is a more recent choroiditis, with a patch near the macula but small. The vision in this eye is 0.3. She has never menstruated or borne children, on account of the complete closure of the os uteri. Since the catamenial period, she has always suffered with cramps and swelling of the abdomen, at the regular times.

In illustration of the effect of the menopause, in predisposing to bad troubles of vision, I will cite the case of a Miss K. at 55. She is stout and healthy but not plethoric. Seven weeks ago, while reading, she suddenly lost the sight of the left eye. When first seen she could only count fingers at six feet distance.

She has extensive retinal hæmorrhages, with blood coagulæ in the vitreous, but no pain or increased tension. The right eye has a manifest hyperopia of idioptrics. With this corrected the vision is perfect. Her age and pulse indicate some calcareous degeneration of the coats of the arteries. But without the fullness resulting from cessation of menstruation, this fatal trouble would not have occurred.

The sudden seriousness of detachment of the retina is well known. Different explanations of its pathology have been advocated, but that question is not settled. It frequently, but not always, occurs in

highly myopic subjects. Now and then eyes of normal refraction are attacked. A man of healthy appearance, 37 years of age, went suddenly blind in the right eye two years ago. The left is perfectly sound and vision normal. The detachment is extensive, and below. About the time this came on, partial hemianesthesia of right side of face and scalp was discovered, and still persists. The derangement of feeling is strictly confined to the distribution of the supra-orbital branch. Lately he has suffered with severe pain in the teeth of his left side. These are the only symptoms. What effect has irritation of the fifth nerve, if any, on the etiology of detachment of the retina?

In some cases of retinitis pigmentosa, a very peculiar disease, there are seen unusual and troublesome complications, that require explanation. I recall a maiden lady with this form of retinitis. One eye was already blind. In the other the concentric narrowing of the field of vision was slowly increasing. In the right eye, already blind, there was confirmed glaucoma. She came to me with an acute attack of the same disease in the left eye. I made at once a large iridectomy, which arrested the glaucoma. Seven or eight years have since passed, and she still sees a little. Final blindness is inevitable, but the evil day was put off by the operation.

Miss B., aged 16, was first seen March 16, 1883. She then had keratitis of fifteen months in the right eye, and three months in the left. The corneæ were hazy and vascular, and the deeper media turbid. With the ophthalmoscope glimpses of the fundus were seen, indicating retinitis pigmentosa. The right eye was convergent and amblyopic. She had experienced night blindness since childhood. The vision of the left eye was 0.3. She had Hutchison's teeth, and the peculiar physiognomy of inherited syphilis. When seen again, in one year, the corneæ were nearly clear, but vision about as at first visit, being able to read ordinary print at 8 inches. There was then contraction of the field of vision, advanced atrophy of both optic nerves, and the usual deposits of pigment in the retina. By this time the media were clear, and we saw the sharply defined, characteristic patches in the choroid, of choroiditis circumscriptæ, as well as the retinal pigment. This case goes to confirm the view that the so-called retinitis may be, primarily, a disease of the choroid. What connection the specific inheritance had with the latter diseases, I do not venture to conjecture.

An only child, 3 years old, born with syphilitic eruptions on the face and body, that were long in disappearing and left scars, was lately brought for advice. The child was rickety, and long in learning to walk and talk. The father has a clear, specific history. For several months the child had been somewhat intolerant of light, but for four weeks the photophobia has been intense. Both corneæ were cloudy and partially vascular from parenchymatous keratitis. It is a case of Hutchison's syphilitic inflammation of the cornea. The diagnosis is certain, though the peg teeth are not present. The result of treatment is yet undecided.

Take the following for its hopelessness and ob-

scurity: M. A., aged 9, a delicate-looking girl, has had marked divergence of the right eye from infancy. With the left she could see well till one year ago, when it began to fail. For the last three months she has lost rapidly in sight. In the right there is absolute blindness, with extinction of perception of light. She still reads Snellen No. 8 slowly, and objects in the outer half of her field are better seen than elsewhere. There is pronounced white atrophy of the optic papillæ. No cause can be detected in the brain or spinal cord to account for it. For two years the gradual failure of sight is the only symptom. Lesion in the nerve centres, not yet revealed by other symptoms, is certainly to be inferred.

For difficult diagnosis, let us describe the case of a German woman, 38 years old, well developed and healthy. About a year since she found that the vision of her left eye was defective. Three months ago the right began to fail. For the past year she has been much troubled with giddiness.

These attacks, with tendency to stagger and fall, have occurred at different intervals, but never oftener than once in two weeks. No nausea or vomiting, but numbness confined to the hands was often felt. She has not menstruated for four years. An enlargement of the abdomen resembles pregnancy, which does not exist. Within a year she has grown very fleshy but lost strength. The vision in right eye is 0.8. With the left she counts fingers only at 6 inches. In this eye the papilla is quite blanched, but in the other it is normal, and the color sense is perfect. The field of vision is quite clear in its inner half, but dim in the outer half. In the left eye, the outer half of the field of vision is totally abolished. She now has frequent and violent attacks of headache. We ordered moderate doses of iodide of potassium, and in two months she returned, quite relieved of the pain in the head. Vision with the right eye was now perfect, or nearly so. The left could count fingers at 6 feet. But the hemianopsia remained the same, as did the ophthalmoscopic appearances. The diagnosis was atrophy of the left papilla, and hemianopsia in the outer halves of the field of vision. This means loss of perception in the *inner half* of each retina. History and symptoms all indicate a brain lesion. The seat of the difficulty is conjectured. Time, and a post mortem may determine the seat and nature of the trouble.

Every surgeon of pretensions, and all mountebanks operate for strabismus, as though the problem of cure were entirely mechanical. The influence of associated convergence and accommodation, in causing strabismus, and the certain changes produced by the progress of years, are not thought of. Immediate results may be satisfactory and remunerative. But insufficiency of the divided muscle, and subsidence of accommodation, will probably lead slowly to great and unsightly divergence, a deformity far worse than the original, and vastly more difficult to relieve. Then again careless and ignorant operators often get no effect, because of inexact diagnosis, not knowing that the case was due to paralysis. Very recently I was asked to operate for squint on a delicate married lady of 36 years. Both eyes were

turned far inwards with no ability to rotate either outwards. When but three months old, sleeping in a draft between two open windows, she awoke with the eyes turned in from paralysis of both external recti. Complete paralysis, of 36 years, leads to atrophy of the inactive muscles and rigid contraction of the antagonists. She had never learned binocular vision. No hope can be entertained of restoration to a physiological condition. Hence, no satisfactory result could come from a simple tenotomy, and a tedious operation for advancement, might only result in distressing and life-long double vision. This is the more to be apprehended, as the vision in both eyes was equal and perfect. For these reasons I refused to operate.

A CASE OF EXTRA-UTERINE PREGNANCY.

BY C. N. COOPER, M.D.

Mrs. C. consulted me in October, 1882, for what she supposed to be some uterine disease. She was English by birth, 39 years old, and the mother of four children. She had suffered three miscarriages. Her youngest child was four years old. I treated her nearly three months for subinvolution previous to her last pregnancy. For the past eight months her menstrual flow had been scant, and followed by a somewhat profuse leucorrhœa. She had no flow in September, but when she consulted me, had recently ceased from her October period, and was suffering from dragging pain, lassitude, etc. I found the os flabby and patulous, readily admitting the point of the index finger. The cervical canal seemed filled with tenacious mucus. The depth of the uterine cavity including the cervix was five inches. Three times each week for the first month, and twice each week for the second month, I applied equal parts of tincture iodine and fluid extract ergot to the cervix, within and without, and occasionally carried the treatment to the fundus; also, ordered free, hot vaginal injections at bed time. After two months treatment the uterus had increased to 6½ inches in depth, and the os was still patulous, but the leucorrhœa had ceased. A tumor could readily be felt either within the wall of the uterus or attached immediately to it upon the right side. It did not seem to encroach upon the uterine cavity.

By the first of January the tumor was as large as a pregnant uterus at the beginning of the fourth month. Its position was always on the right side, and freely movable with the uterus. The patient thought she could feel motion within the tumor, yet no foetal heartbeat could be detected, and the breasts were but slightly enlarged, if at all. The rapidity of the growth, and the fact that somewhat rough manipulation over the abdomen caused some degree of contraction, which was apparent to her as well as to myself, taken together with the supposed motion, led me to the conclusion that the case was one of tubal or interstitial pregnancy. There was considerable pain in the

right iliac region, sometimes extending down the thigh and leg. The patient declined a consultation, and about the middle of January she suffered so much inconvenience, I put her on the use of iodide and bromide of potassium. No special change occurred in the case until the middle of February, when I was called in haste, and found her in apparent labor. Pains had been occurring every five or ten minutes for about two hours. The contracting tumor could not be compelled to retain a central position except when held there. I found the os uteri dilated sufficiently to admit two fingers, and by pressing the mass well down, I could detect a sac bulging from the right side of the uterus. From this time I kept the tumor within my grasp, and increased the pressure during the pains, which now recurred every three minutes.

Within half an hour there was a free flow of water, the os was dilatable, and I could distinctly feel a head presenting where I had before felt the distended sac. I had not long to wait before the head presented at the well-dilated os, and the progress of delivery was uninterrupted. The foetus was a male of apparently six months' development, though rather small. Life was not entirely extinct, but resuscitation was impossible. The afterbirth was thoroughly delivered in eight minutes. The lochia continued about four days. The breasts did not fill sufficiently to require any attention. The patient suffered no unusual difficulties in getting up, except a constant sore and dragging feeling in the right groin. The tumor did not disappear from the right side for about six months after delivery. On subsequent examination I found no trace of the tumor, neither could I find any indication of a double uterus. All her other pregnancies had been natural in appearance and position. Whether this pregnancy should be called tubal or interstitial I cannot say, but that it was entirely outside of the uterine cavity there is no room to doubt.

The happy termination of this case was certainly rare, and has led me to think of the possibility of operative procedure through the easily dilated os in cases of extra-uterine pregnancy where the foetal mass is within, or in immediate proximity to, the wall of the uterus.

Batavia, Ill.

MEDICAL PROGRESS.

MATERIA MEDICA AND THERAPEUTICS.

NEW REMEDIES FOR PSORIASIS.—The *British Medical Journal*, in an editorial, gives a very satisfactory review of this subject. Chrysophanic acid still holds a conspicuous place. Its effect in curing psoriasis is undoubted; and if it be not universally employed, it is more on account of the inconveniences connected with its use than from any doubt of its real efficacy. Several ingenious methods have been lately introduced, with the object of remedying these in-

conveniences. Pick recommends a mixture of gelatine and chrysophanic acid in different proportions.

Auspitz uses "traumaticin" instead of gelatine, traumaticin being a solution of one part of purified gutta percha in ten parts of chloroform. This preparation adheres closely to the skin, and remains from two to three days without change. Gelatine, on the contrary, becomes detached within several days by the rubbing of the clothes or the movement of the limbs. Traumaticin forms a much thinner and more delicate pellicle than either collodion or gelatine, and is more easily borne; and as applications made with the solution of the strength of 10 per cent. have never provoked irritation, even when applied to considerable surfaces, either in children or in adults—the chloroform evaporating slowly, and the gutta percha becoming only gradually hard—it is easy, whilst making an application, to rub it well in upon a considerable number of patches. By means of this rubbing the scales can be removed, and the chrysophanic acid directly applied to the bare and bleeding patches.

The method of Auspitz is carried out in this manner: After the scales have been removed by means of a bath and application of soap, all the patches are dabbed and rubbed with a brush steeped in a mixture of the strength of 10 per cent. If the affection be not extensive, the application is renewed each day. If it occupy a large extent of surface, it is renewed only in two or three days. If the scales be in considerable quantity, a soap bath is prescribed. If the scales be not very plentiful, soap lotions are sufficient. After one or two rubbings many of the patches appear flat, and in general the scales persist only on the borders of the patches. After two, or at the most a dozen applications, according to the intensity and extent of the psoriasis, the infiltration and scales disappear, and in their place are found white patches surrounded with a red or violet-brown border. When the disease is limited in extent, one application renewed daily for three to six days is sufficient to cause the patches to disappear, without the necessity of having recourse to lotions or baths.

M. Besnier modifies this method of Auspitz. After removing the scales, he rubs the patches with a common house-painter's brush, soaked in the mixture of chloroform and chrysophanic acid at 15 per cent. The duration and energy with which the application is made, should vary according to the thickness of the patches of psoriasis. The application gives rise to a slight sensation of heat and smarting; in a few seconds the chloroform has evaporated, and the patch is literally infiltrated with pure chrysophanic acid, having become of the deep yellow color of iodoform. It is only then that, with a large flat brush, the patch is covered with a layer of traumaticin, which must be thickly laid on, and which extends beyond the border of the patch. He has applied this method even to parts covered with hair; it has been found useful chiefly in cases of moderate infiltration, but when the patch is thick, fissured, and desquamating abundantly, the effect is not so striking. In such cases M. Besnier has used, instead of chrysophanic chloroform, a 10 per cent. solution of pyrogallallic acid in ether, which is then immediately covered with a layer

of traumaticin, but this latter substance must be applied to the skin with great caution, several cases having been reported in which fatal results followed its absorption.

OBSTETRICS AND GYNÆCOLOGY.

THE APPLICATION OF ANTISEPTICS TO MIDWIFERY. —Arthur V. Macan, M.B., Master of the Rotunda Hospital, treats at some length of this subject in his report of the Rotunda Hospital for the year ending November 3rd, 1883. (*Dublin Journal of Medical Science.*)

The first rule made by him, after being appointed Master of the Rotunda, was that no student who was dissecting would be allowed to enter the hospital; vessels containing a 1 in 40 solution of carbolic acid were placed over every wash-hand basin, and he personally instructed every student who entered the hospital as to the way he thought it necessary to wash the hands. A notice was also put up in every ward, viz., "No one shall make a vaginal examination without having first washed their hands in carbolic acid solution, using a nail brush carefully."

Moreover, to lessen the necessity of making vaginal examinations, and thereby also the risk of conveying septic infection, each student is taught to palpate the abdomen, and soon recognizes without difficulty, except in exceptional cases, not only what the presentation is, but also the exact position of the child's head, back, and limbs. Also every student or nurse who examines a woman *per vaginam* has to write his or her name down on her card, so that if she should afterward prove to be infected the origin of the infection may be traced. This can readily be done, as only four students are allowed to examine any given case. As soon as the child is born, the woman is made to lie slightly on the back to prevent the entrance of air into the vagina or uterus, and there is an absolute rule against touching the woman's genitals with the fingers after delivery, except in cases of post-partem hæmorrhage, ruptured perinæum, or retained placenta, and then only by the Assistant Master. Before stitching up a ruptured perinæum, the vagina is injected with carbolic acid solution (1 in 40), and, should it be found necessary to introduce the hand, the uterus is always washed out with a similar solution. (For some months past a solution of corrosive sublimate, 1 in 2,000, has been substituted for the carbolic acid, with most satisfactory results.) In like manner the vagina is irrigated and the external genitals are carefully washed before every operation, and the uterus is syringed out afterwards, and recently a pessary containing 3jss of iodoform has then been passed to the fundus and left there.

To prevent the possibility of infection being carried by a vaginal or uterine tube, they are all made of glass, and a separate vaginal tube is provided for every bed in the hospital. These, when in use, are kept in carbolic acid solution, and are boiled in the same solution before being again used for another patient. The old India rubber syphon syringes have been entirely replaced by irrigators, which act by gravity,

and carbolic acid solution is constantly evaporated in the wards day and night. The old gum-elastic catheters have also been banished, and their places filled by silver instruments; which, both before and after being used, are placed for a considerable time in the hot evaporating carbolic solution.

He never allows any prophylactic antiseptic injections, whether vaginal or uterine, not considering it even necessary to use an antiseptic solution for washing the external genitals, which is done twice daily with plain, warm water, a piece of oakum taking the place of a sponge. Such are the precautions taken against hetero-infection. In auto-infection he attempts to meet two dangers; first, the foetid discharge, and second, the retention of this discharge within the uterus. For the first, air must have been allowed to enter the uterus. One point of great importance, in order to prevent this, is to make the woman lie somewhat on her back as soon as the child is born. If this be not done, and the pressure of the hand is removed for a moment from the fundus, the uterus falls downwards, a vacuum is formed, into which, if the sides of the vulva from any cause, such as ruptured perinæum, are not in close apposition, air rushes. He insists, for the same reason, on the maintenance of the position on the back for some days after delivery, and the proper application of the binder. This is also of value in preventing an accumulation taking place within the uterus, as the intra-abdominal pressure is greater than when the woman is on her side, and gravity acts more thoroughly. Should the discharge become foetid *hot* antiseptic vaginal injections are indicated, which cause the uterus to contract. If the discharge be foetid and the temperature not only becomes high, but remains so for twenty-four to thirty-six hours, then intra-uterine antiseptic injections should be made, and an iodoform pessary introduced. If no signs of inflammation be present, the patient is encouraged to get up on the sixth day as usual. The erect position, by aiding gravity, and putting increased pressure on the fundus, causes the drainage to be more perfect, and the result is, as a rule, that the temperature quickly sinks to normal.

The iodoform pessary includes 3j to 3jss of the drug. It decomposes very slowly and exerts its antiseptic action for three or four days. It has a powerful effect in lessening the temperature. In the antipyretic treatment large single doses of quinine are given, 10 to 20 grains, or the bath at 90° cooled down to 60°, both combined with large quantities of alcohol. This latter measure, however, has only been resorted to once.

To show the effects of these modes of treatment, these statistics give 6 deaths out of 1,090 deliveries during the year. This mortality is *from all causes*, and there was not a single transfer of a puerperal woman to any other hospital. Among these cases there were 62 forceps, 29 breech, 16 abortions, 8 placenta prævia, 5 version, 8 adherent placenta, etc. Barnes' forceps were the favorite, Tarnier's being too large. Hegar's modification of Simpson's modification of Tarnier is well spoken of. 25 cases of post partum hæmorrhage, or only 1 in 43.6, speak

well for the treatment of allowing at least fifteen minutes to elapse before expressing the placenta, the uterus being gently rubbed and kneaded during that time. In 6 cases of puerperal convulsions the treatment was chloroform, morphia subcutaneously, enemata of chloral hydrate (30 grains). Hot steam baths and pilocarpine subcutaneously ($\frac{1}{3}$ grain) in albuminuria and oedema. Dr. Macan was not able to recognize any constant rise of temperature, even to the extent of one degree, accompanying the first secretion of the milk. The report of the external maternity comprised for the year, 1,335 cases, of which 100 were abortions, 42 breech, 29 forceps, 7 placenta prævia, and 7 adherent placenta.

SURGERY.

THE CONVERSION OF MALIGNANT TUMORS INTO INNOCENT GROWTHS.—Prof. v. Nussbaum, in a clinical lecture recently delivered in Munich (*Wien. Med. Zeit.*), expressed the belief that he had discovered a procedure for the positive cure of cancer by restraining the proliferation of the tissue elements of the disease. It appears to him that a total interruption of all peripheral sources of nutrition is the means best adapted to secure this result. He accomplishes this object by the use of the thermo-cautery, with which instrument a deep channel is made quite around the malignant growth, thus cutting off entirely the supply of blood and other nutritive fluids from the surrounding tissues. The small vessels which ascend into the tumor from the parts beneath are sufficient to preserve its vitality, so that gangrene does not occur. He thinks the thermo-cautery far preferable to the ligature, and that it possesses many advantages over the knife. He regards the hot iron and the various chemical caustics worthy of more extensive employment in the domain of malignant growths than they have ever enjoyed. Prof. Nussbaum doubts not that this circumscribing a cancerous growth, thus cutting off every channel of peripheral nutrition, has a brilliant future, especially in those desperate cases in which death is imminent from hæmorrhage. In his experience, this method of cutting off the peripheral blood supply has afforded such astonishing results that he recommends this procedure to the attention and practice of all those having occasion to treat a case adapted to its employment.—*Birmingham Medical Review*.

PNEUMOTOMY.—The *Medical Times* has been publishing some interesting cases in which pus-secreting cavities in the lungs have been opened and drained externally with considerable success. There has also been an interesting discussion on the subject at the Royal Medical and Chirurgical Society, following the reading of a case in which this operation had been successfully accomplished by Mr. Gould, at the suggestion of Dr. Cayley. The patient was a girl about twelve years of age, suffering from a local gangrene of the lung of acute onset; other remedies had failed, and the girl was rapidly losing ground, when it was decided to puncture the lung and endeavor to

drain the cavity of its gangrenous contents. So successfully was this accomplished, that a sequestrum of gangrenous lung was evacuated, and the patient made an excellent recovery. Dr. Biss subsequently related a case in which a basic abscess, with foetid contents, had been diagnosed and a similar plan of treatment carried out by Mr. Marshall. The case was of a more chronic nature than the preceding, and not so easy of diagnosis. As might have been anticipated, it was less successful, but nevertheless the operation afforded the patient considerable relief during the short remainder of his life, and death was in no sense due to the operative measures adopted. Dr. Fowler gave the particulars of a very unusual case, that of a man who had swallowed a molar tooth. Disease of the lung with formation of a cavity in the base supervened, and threatened to prove fatal. The tooth was not removed, but the abscess was drained with a fair amount of success. Mr. Goodlee, Dr. Broadbent and Mr. Walsham related cases in point. In all alike, the advantages of freely draining away the pus were manifest, even when, from the nature of the case, a permanent cure was not attainable.

The operation consists in opening the abscess cavity, and putting in a drainage tube. It is variously done, either with or without previously incising the chest wall.

Thus Mr. Gould passed in a large trocar and canula, and, after withdrawing the trocar, introduced a drainage tube, and then withdrew the canula, leaving the tube in the cavity. Mr. Marshall cut down on the pleura, and after exposing it, pushed in his trocar to the depth of four inches. Mr. Goodlee, in his cases, excised portions of ribs, and used a scalpel, after having explored with a hollow needle in the first instance. The amount of hæmorrhage appeared to vary, but in none of the cases was it severe, and in none was there any difficulty in arresting it. As regards the pleural cavity, while most of the speakers agreed that it would be better if it had been obliterated by adhesion, some seemed to think that the importance of its obliteration had been exaggerated.

The editor in his remarks inclines to the view that a healthy pleural cavity, could it be diagnosticated, would be a strong contra-indication, as a case within his knowledge proved that the accidental introduction, even of small portions of gangrenous fluid into a healthy, pleural cavity, can be followed by severe inflammation, and possibly by gangrenous empyema.

MEDICINE.

LOCALIZED SWEATING IN LOCOMOTOR ATAXIA.—Besides such phenomena as the altered conditions of the pupils, the gastric, intestinal, and vesical crises, the permanent acceleration of the pulse which has sometimes been observed, the alterations in the secretions of the alimentary canal, the cutaneous ecchymoses and eruptions, and the affections of the nails and joints, which point to an affection of the sympathetic nervous system in locomotor ataxy, we have now added alterations in the functions of the sweat-glands. In the *Revue de Médecine* (*Med. Times*),

M. M. Raymond and Artaud describe the case of a man, aged 46, who was the subject of ataxy, and who presented a well-marked sweating confined to the right side of his face after each meal. This came on in from ten minutes to a quarter of an hour after the meal, and was not associated with any change in the pupil; the sweating occupied the corresponding side of the head and neck, extending to the shoulder. There was no affection of smell or taste, but the patient said that there was increased flow of saliva on the affected side during the sweating. The injection of pilocarpine did not seem to cause more sweating on one side of the face than the other. The authors mention that they have already recorded two cases in which the sympathetic ganglia were found to be affected *post-mortem*, and they allude to Pierret's view, that the central region of the sympathetic lies in the posterior vesicular columns and tractus intermedio-lateralis of Clarke, a region which is very commonly found to be sclerosed in cases of locomotor ataxy.

EXOPTHALMIC GOITRE.—In the *Ophthalmic Review* Dr. James Russell contributes a case of Graves' disease presenting some features of interest (*Med. Times*). The patient was a girl, aged 16 years, who presented decided exophthalmos on the left side only.

The lids of the right eye were retracted, producing the well-known staring appearance. In the neck there was a very small goitre, alike on the two sides. The mother said that at first the two eyes were equally prominent, and that after a time the right eye went down; though it did not regain its natural appearance, the goitre had varied but very little since it was first noticed. The patient was said to have suffered from palpitation, but made no complaint of this whilst under observation. The pulse was repeatedly examined, and was seldom above 100; it was generally under 90, and several times was less than 80. In a note appended after the paper was written, Dr. Russell states that on subsequent examinations of the pulse the average frequency of the beats had been much greater, being above 110 on a majority of occasions of examination. With this there had recurred a certain amount of exophthalmos of the right eye, though not to the same degree as in the other eye. This case seems to confirm a suggestion made by Dr. Fitzgerald in the same journal, that when the cardiac symptoms are absent the other symptoms should preponderate on the left side.

ON THE VALUE OF ISOLATED SYMPTOMS IN THE DIAGNOSIS OF DISEASE IN CHILDREN.—Politzer (*Jahrbuch für Kinderheilkunde*, Edinburgh *Clinical and Pathological Journal*) gives his experience, extending over more than forty years, in the Vienna Children's Hospital:

Nasal or Palatal Cry.—This is present in ozæna, generally caused by congenital syphilis, and in hypertrophy of tonsils. If not due to either of these causes, it is diagnostic of retro-pharyngeal abscess. The pharyngeal wall should always be carefully examined in such cases.

Prolonged and noisy expirations, with normal in-

spiration, and no sign of asphyxia, is met with in chorea major.

Sighing inspiration, which seems to originate in the upper part of the chest, indicates cardiac weakness and paralysis, sometimes fatty degeneration of the organ.

Harsh and loud diaphragmatic expiration indicates bronchial asthma.

A pause between the end of expiration and the commencement of the succeeding inspiration, points to laryngeal catarrh, associated with spasmodic laryngeal stenosis, with submucous oedema.

Continuous stridulous respiration from birth, indicates faulty innervation, due to inhibition of the vagus.

Drowsiness occurring in children, is often the first sign of basilar meningitis.

Fulness of anterior fontanelle, with feeling of resistance, is also frequently an early symptom of basilar meningitis. This is generally present in all inflammatory affections of the brain, also fevers complicated with cerebral mischief.

Depression of anterior fontanelle, usually accompanied by sunken eyeballs, shows diminished quantity of blood in the brain.

Slow movement of eyeballs, with a vacant, staring look, points to basilar meningitis.

Violent and shrill cry, lasting two or three minutes, with anxious expression of countenance, occurring an hour or two after going to sleep, indicates "night terrors." It is generally met with in delicate, nervous children.

A periodic cry, occurring during the day or at night, accompanies colic and gastro-intestinal derangement; also, dysuria and painful contraction of the bladder.

Cry accompanying defecation, is generally associated with constipation, and often with fissure of the anus.

A continuous, painful cry, with turning about of the head on the pillow and putting the hand up to the head, indicates otitis.

Persistent crying for weeks, aggravated by handling the child, and movements of the limbs, associated with fever and sweating, probably indicates rickets.

Cry of sleeplessness is often associated with congenital syphilis or chronic indigestion.

A similar cry to the last mentioned is often met with in chronic diarrhoea or purulent discharges, associated with thickening of the blood.

Physiognomy of congenital syphilis is pathognomonic.

Collapse of the nostrils, and absence of alar movement, indicates great hypertrophy of the tonsils.

A disinclination to move may indicate the beginning or existence of spinal paralysis.

Sluggishness of intellect, after brain disease, may indicate acquired idiocy.

Delayed ossification of cranial bones indicates rachitis.

Constant vomiting, occurring when the fontanelles are closed, indicates acute mischief in chronic hydrocephalus.

SATURDAY, AUGUST 2, 1884.

PARTIAL OPTIC NERVE ATROPHY IN LEAD POISONING.—Dr. Uthoff,¹ of Berlin, publishes two cases of well-marked central blindness associated with normal peripheral visual acuity, which he refers to lead poisoning. Both male patients, one 57 and the other 18 years old. Both came under his observation about a year after the commencement of the trouble. The optic-discs, especially the temporal halves, exhibited well-marked atrophic change, whilst the nasal halves, although paler than normal, exhibited a pinkish color. Both patients were markedly asthenopic, being able merely to count fingers at a distance of six or seven inches, and each eye exhibited a well-marked and relatively large central field of absolute blindness, whilst the peripheral vision was normal. The one of 18 years was a painter's apprentice, and was attacked one month after the commencement of his apprenticeship. He had been working with white lead. At the outset his sight seemed to improve, but finally remained in the condition indicated. The other manifestations of lead poisoning disappeared. The difficulty appeared suddenly, and was associated with vertigo.

The second case, of 57 years, was a worker in a rubber factory, in which lead was used. In the years from 1854 to 1868 he had several times suffered from lead poisoning, as exhibited by lead-colic, contraction of the left forearm, pain in the left leg, and later on, emaciation of the left arm. In 1866 occurred a certain mental disturbance which disappeared when he quit his work. In the same year he suffered from

a clouded condition of the sight. From this time up to 1882 he was in good health, notwithstanding that he was again at work in the rubber factory. A small fire breaking out in the workshop, he exerted himself to the utmost to extinguish it, and then, overcome by the exertion, he was senseless for a short while. From this time he dated the peculiar visual disturbance, which at the first seemed to improve, but afterwards it remained with a central defect of vision, amounting to about 15° in every direction from the point of fixation. There was developed at the same time with the disturbance of vision a certain stiffness of the legs, resulting in an unsteady gait. The general conditions improved, but the visual anomaly remained, and the pupils were insensitive to light. In neither case was there albumen in the urine.

SPASM OF THE ORBICULARIS AND POSSIBLY CATARACT DUE TO DENTAL IRRITATION.—Mr. H. Sewill, M.R.C.S., reports an interesting case in British Medical Journal, May 10, 1884, of which the following constitute the main features: A nervous middle aged spinster with facial spasm and neuralgia on the right side of the face and head, associated with spasm of the orbicularis. There was great tenderness in the region of the right upper canine; the neighboring teeth were much encrusted with tartar and the gums were red and swollen. The lens of the right eye is said to be "almost opaque." Dr. Ferrier, who examined the case, supposed that the dental irritation was the cause of the trophic disorder leading to cataract.

Examination of the mouth revealed a vulcanite plate which had not been removed "for years," and together with the teeth was covered with tartar. The whole of the teeth were carious, but the right canine was broken down nearly to the gum with considerable swelling extending upwards over the root. Pus could be pressed from small fistulous openings over the roots of all the teeth. The lower teeth, ten in number, were hidden beneath a mass of tartar which extended a half an inch over the floor of the mouth. Within two days after the extraction of the teeth the spasm entirely disappeared and the patient's health rapidly improved, but no change took place in the damaged lens.

The above case is cited not as a proven case of cataract due to dental irritation, but as at least a not improbable one.

CHOLERA REPORT.—The news for the present week from Marseilles and Toulon is more favorable.

¹ Beiträge z. Pathologie des Sehnerven, etc., 1884.

Cooler weather has prevailed, and the rate of mortality has been materially diminished. Admiral Krantz, in command of the fleet at Toulon, telegraphed under date, July 28, to Paris, that he is sanguine of a daily diminution in the number of deaths in that city.

Cases are numerous in the suburbs of the cities named, but the progress of the epidemic is not so rapid as we had reason to fear.

The rumor of the introduction of cholera to St. Louis, by the way of New Orleans, is entirely without foundation, as appears from the report of Joseph H. Holt, President of the Louisiana State Board of Health to Surgeon-General Hamilton, of the Marine Hospital Service.

We have reason to believe that the authorities by sea and by land are moving with commendable activity, to arrest so far as human agencies can, the progress of the impending scourge.

ABOLITION OF MARINE-HOSPITAL DUES.—Section 15 of a bill recently passed by Congress, reads as follows:

“SEC. 15. That sections forty-five hundred and eighty-five, forty-five hundred and eighty-six, and forty-five hundred and eighty-seven of the Revised Statutes, and all other acts and parts of acts providing for the assessment and collection of a hospital tax for seamen, are hereby repealed, and the expense of maintaining the Marine Hospital Service shall hereafter be borne by the United States out of the receipts for duties on tonnage provided for by this act; and so much thereof as may be necessary, is hereby appropriated for that purpose.”

This puts an end to the collection of a tax on sailors to support the Marine Hospital service, and substitutes therefor so much as may be necessary of the revenue derived from the tax on the tonnage of vessels. The vessel owners, and not the sailors, will hereafter bear the burden of supporting the system of Marine Hospitals throughout the whole of our country.

SEWERAGE EPURATION.—In this and the preceding number we publish the excellent and important paper of Dr. Barnes, presented to a Section of the Suffolk District Medical Society of Massachusetts, on this subject. It was placed on file for the JOURNAL three or four weeks previously, but was postponed from pressure of other matter. At the present time, when so much of attention is given to sanitary matters, on account of the threatened invasion of epidemic cholera, the paper of Dr. Barnes is opportune, and should be carefully read, not only by all engaged directly in

sanitary work, but by every practicing physician. For the question how to dispose of the sewage and waste organic material necessarily accompanying the aggregation of the human race in families and permanent communities, in a harmless and profitable manner, is one of paramount importance, not only to large cities and densely populated communities, but also to every isolated institution and family. And no other member of human society can exert as much influence in giving direction to this and every other variety of sanitary work, as the active practicing physician, whose influence extends into almost every household, whether in city or country.

SOCIETY PROCEEDINGS.

SEWERAGE SYSTEMS AND THE EPURATION OF SEWAGE BY IRRIGATION AND AGRICULTURE.

BY HENRY J. BARNES, M.D.

(Continued from last week.)

PRECIPITATION BY CHEMICAL MEANS AT COVENTRY, ENGLAND.

Population 40,000. Five thousand water closets connected with the sewers, which discharged 2,289,000 gallons of sewage in the river Sherborne. Complaint and litigation was the result. A reservoir of deposit was constructed, after which the sewage was allowed to filter across a gravel bed three feet thick. This proved unsatisfactory, as only solid matter was taken out, and the court again interfered with an injunction. A contract was then made with a fertilizer company, which agreed to epurate the sewage for fourteen years at \$3,750 per year, the company engaging to erect buildings and machinery, and furnish the necessary tools. An extractor first separates the solid matter. The liquid is then run into caldrons under the first group of buildings. Agitators mix impure sulphate of alumina with it at a boiling temperature. It then passes into a second set of vessels, where milk of lime is added and thoroughly mixed, then discharged alternately into four reservoirs in the open air, which are cleaned every fourth day. The liquid thus treated comes out sufficiently pure, and is allowed to filter over about four acres, and finally find its way into the river. Thirty tons of detritus are taken each day from the reservoirs, piled to dry, and subsequently treated by artificial heat. The works are not in operation at night, except the discharge of the sewage on the filter beds. Twenty-two tons of coal, one ton of sulphuric acid, nine tons of sulphate of alumina, and four tons of lime are used each week. The company's net loss is about \$7,500 each year.

After long and costly experiments the greatest

“Millions of dollars have been expended in France in chemical experiments on sewage, all of which have been condemned.” *J. Babut du Maris.*

chemists have declared that in practice the only manner to epurate sewage is to send it on the land, which eliminates the polluting elements and fertilizing matter for the good of vegetation and the soil. Dr. Angus Smith says: "In all cases the best results are obtained by irrigation." And Dr. Carpenter certifies in a notice read at the International Congress in 1881 "the only way ammonia can be eliminated from sewage is by irrigation."

A commission appointed by Parliament, composed of Messrs. Dennison, Frankland, and Morton, reported: "The actual resources of chemistry do not permit the hope that the polluting matter dissolved in sewage can be precipitated and sent away by any appliance of chemical reaction, and unless new chemical laws are discovered it is useless to attempt the employment of chemical agents. Epuration must be confided to Dame Nature."

At the Women's Prison in Sherborn, Mass., epuration of sewage is attempted by what is known as Colonel Waring's method. Five acres of land are here employed, in the water-shed of Lake Cochituate, about two miles from the lake, with which it is connected by a brook, one of the tributaries of Boston's water supply. The sewage is distributed over the land by tile-drains with broken joints laid fourteen inches below the surface, five feet apart. The effluent drainage is provided for by cross sections of tile laid five feet under ground, which after collecting the water, discharge in the brook. This system is said by the prison authorities to work satisfactorily.

"The water coming from the ground is as clear as spring water, and was selected by an expert as such on inspection." This only indicates clarification, and we regret that analyses made were not published, as no one seems to know where they are at the present time. There can be no doubt but the grass, which is the vegetation on the land, takes nourishment from the sewage, for the lines of drain are clearly marked by a better growth directly over them, which does not extend to the intervals between. One of the defects of this system has already been experienced. Insoluble matter has filled the interstices between the tiles, and prevented fluids from passing through, necessitating their being taken up and re-laid. At a depth of fourteen inches the influence of vegetation and the infusoria must be lost on much of the sewage, which was probably disclosed by the analyses, rendering it desirable, that they should be pigeon-holed. (Since writing the preceding a visit to the prison more than confirms the anticipated objection to the system). And the following analysis obtained in the office of the State Board of Health is proof beyond dispute that the system amounts to nothing by way of purifying the sewage, and that it is practically a mammoth cesspool, the contents of which the citizens of Boston must drink:—

WOMEN'S PRISON SYSTEM. PARTS PER 100,000.

	Ammonia.	Alb. Ammon.	Chlorine.	Residue.
Supply End.	.240	.018	9.58	68.5
Flow End.	.232	.034	9.22	69.0

The exclusion of air from the sewage of this system keeps it fresh, the nitrogen is in an organic state, and consequently of no use to vegetation. A fertilizer should become ammoniacal by decomposition before it is possible of assimilation by plants. Analyses of sewage in Europe reveal the fact that there is no loss of fertilizing material in a closed conduit having a run of seven and one-half miles. And examinations of the soil of sewage farms show that in all instances the sand one foot below the surface is as pure and white as that where irrigation is not practiced.

In the Mystic valley the sewage of tanneries has for several years been pumped by the city of Boston into reservoirs of deposit obviously too small to eliminate even the matter in suspension. From the tank there is an overflow into a shallow ditch several hundred feet long, in which are set several brush dams, after which it discharges into the Mystic lower basin. The result of this treatment is to start putrefaction by warmth and free exposure to air, and thus produce a stench which people living in the vicinity claim has greatly reduced the value of real estate. It does not merit extended description, as the effort thus far made merely amounts to a flirtation with the subject.

A few of the farmers living along the Blackstone river are beginning to appreciate the valuable fertilizing material conveyed by the current from Worcester, Mass. One farmer states that his meadow lands which were practically abandoned, it not paying to harvest the grass, now produce crops which add several hundred dollars a year to the value of his farm. Others are placing obstructions in the river, with the object of turning the water on the land.

During the past ten years sanitarians and engineers have made great progress towards a solution of this question, and it is fair to presume from the great increase in the number of cities and towns that have adopted irrigation and agriculture as the means of purifying sewage that this method has proved the most satisfactory. Berlin has two large farms devoted to this object, one of 2035 acres and another of 1818 acres. A great many chemical experiments were tried before the adoption of the present system. They proved very expensive, and none purified the water, although many clarified it. Finally, after experimenting in irrigation and agriculture for eighteen months on a little field of about three hectares (less than seven and one-half acres), such favorable results were realized that this system was adopted for the city, the eminent Virchow working heartily in its favor. At the present time 1067 acres suffice to purify 15,060,000 gallons per day, the drainage of four-fifths of the city, containing a population of over 600,000. There is some odor at the opening of the large sewer, but in the fields there is no smell, and the sanitary condition is all that could be desired. There never has been any complaint from the numerous adjoining habitations, and the effluent drain water of the farms is pure and clear, it being impossible to recognize by microscopy or chemistry any influences of the sewage. Vegetables and fruit trees grow luxuriantly on the land, and their roots make a perfect filter. Thirteen and one quarter tons of hay

have been cut per hectare (a little less than two and one half acres).

Dantzie, situated about three miles from the Baltic; on account of pollution of its harbor at the mouth of the Vistula, constructed a sewer to discharge on a sandy island having little or no soil, where the occasional tufts of grass were frequently covered with sand carried by the wind. As a result, the island is now in a high state of cultivation. In some parts the land rents to peasants at from twenty to thirty dollars per acre. The frosts of winter do not interfere with the successful operation, as the water delivered by the sewer melts the snow and ice, so that it finds its way into the ground quite as well as in summer, and without injury to the slumbering vegetation. Odessa, Breslau, and Florence also have sewage farms. M. A. Durand-Claye, from whose reports this information is derived, says that "in Germany, it is admitted without question that municipal healthfulness depends upon three principles: first, the total discharge of water-closets in sewers; second, the distribution of an abundant supply of water in dwellings, and frequent flushing of drains; third, the purification of sewage by soil and vegetation."

In England, there are two hundred cities and towns disposing of sewage by irrigation and agriculture. On the farms at Edinburgh are located beautiful nurseries for the children of the city. At Lochend, a farm taking sewage from this city has produced \$200 worth of hay per acre. The Metropolitan Sewer Company of London rents land at \$100 per acre for grazing. Sixteen acres at Rugby furnish feed for fifty-four head of cattle, and at Aldershot, Branbury, Bedford, Croydon, Norwood, Warwick, and Worthing, the reports in detail show an equally wonderful production from the land treated in this manner.

Leamington, with 26,000 inhabitants, spent \$40,000 in chemical experiments, after which the A. B. C. Company, in 1869, attempted to purify the sewage, but gave it up in 1871. It was then allowed to flow into the river Leam. A lawsuit followed, costing the city \$25,000, in which it was defeated, and compelled, at an expense of \$7,500 more, to purify the river. Lord Warwick then consented to receive the sewage on his estates, the city contracting to deliver it at the highest point of the farm for a period of thirty-two years, for which Lord Warwick engages to pay \$2,250 annually. The sewage amounts to a little over 1,000,000 gallons per day, and is distributed over the land, which has not been leveled, by what is known as the "donkey back" system,—elevated open drains, on the sides of which is the vegetation. It has transformed the poorest parts of the farm into soil of much fertility, and financially has proved a great success. From eight to nine cuts of Italian rye grass two feet high are made each year. Celery, strawberries, and currants grow remarkably well. The beef, milk, and butter is in great demand, and bring the highest prices. The laborers are in the best of health, and Lord Warwick has received numerous prizes and silver cups for one of the best kept farms in the kingdom. A more detailed account may be found in Babut du Maris' work.

The Sewage farm at Croydon is surrounded by

beautiful villas, it being a fashionable resort. The land which twenty years ago sold for about \$300 per acre, is now worth from \$2,000 to \$5,000. There has been but one complaint of the farm during the past twelve years, and this resulted from excessive irrigation during a long period of stormy weather, when the hay could not be dried on the land.

A public footpath crosses the sewage farm at Abingdon. There has been no complaint from bad odor.

Babut du Maris says: "It has been claimed that prolonged irrigation will produce disease by the presence of bacteria in the sewage. Experience is to the contrary. The farms at Edinburgh have received the sewage for over two centuries, that at Buntzlau for two and a half centuries, and for more than ten centuries it has been in practice in China. Vegetation has never ceased to be vigorous and healthy, and the inhabitants have never been known to suffer in consequence of irrigation."

I am informed by a gentleman who has resided seven or eight years in China that in all the large cities the detritus is carried into the suburbs by hand buckets and deposited on the lands for the benefit of vegetation, and in many instances the same pails serve to bring back drinking water, with no ill effect except in a few northern cities, where the sewage is put on the leaves of vegetation; there the tape-worm is very common. Dr. Williams, in his work entitled "The Middle Kingdom," does not include typhus, typhoid, scarlet fever, or diphtheria in a list of the prevalent diseases of China.

It is difficult to make comparisons or draw conclusions when considering this question financially, for the paramount objects to be attained vary in different communities. One town may seek only to get rid of the sewage, another its most profitable employment on the land, another relief from the pollution of a water-course or preservation of its navigability; grotesque and unprofitable experiments and local conditions all contributing to make balance sheets of great diversity in showing either profit or loss. Many examples of each are available, and should of course be carefully studied.

The city of Paris, for many years harassed by constant complaint and litigation as a result of discharging sewage in the Seine, some years since established sewage farms on the plains of Gennevilliers, the history of which is told in a report to the municipal council by the sixth Commission appointed to treat with the state for the concession of such public lands at Achères as are necessary for the epuration of the sewage by irrigation and agriculture.

ORIGIN OF THE QUESTION.

Before the execution of the measures conceived by M. Belgrand for the general healthfulness of Paris, the rain water and the washings of the streets flowed into the Seine, either directly, or by a great number of drains emptying on the quays of each bank the whole length of Paris. This mode of drainage resulted in the immediate and pronounced pollution of the water in the river, which reached the maximum at the point where it leaves the city. The work of Belgrand had for its result the concentration of four-fifths of the drain water in a large sewer opening into

the river at Clichy, while the remainder was discharged at St. Denis. At the same time the water for domestic supply was largely increased. In 1860 30,000,000 gallons per day were furnished for this purpose; in 1882 92,000,000 gallons were required each day, or 34,020,000,000 gallons per year. This, with the rain water which falls on the city, estimated at from 9,576,000,000 to 11,340,000,000 gallons, makes a total of 44,100,000,000 to 45,360,000,000 gallons, which, were it not for evaporation and other loss, should be carried by the sewers. This loss amounts to something like 18,900,000,000 gallons per year, as indicated by gauges in the two sewers, which register 26,208,000,000 gallons,—about 42 per cent. disappearing by evaporation. At low water of the Seine it is equal to one part of drain water to twenty of river water, and at high water to one part in 350. As a result of currents and obstacles in the river, mixing did not take place; and the right bank—the most densely peopled—received on a very long margin the totality of the drain water, depositing all the way organic matter brought in suspension. Protestations from people living along the right bank of the river followed very closely the opening of the two great sewers; and the state government required the city of Paris to seriously consider methods of purifying the sewage before discharging it into the river. The savants, engineers, chemists, traders and agriculturists discussed the subject in all its phases, and to the latter we are indebted for practical solution of the problem.

Filtrage was naturally the first system to be tried. It was soon found that, besides the actual difficulties of filtration on so large a scale, this mode of treatment had the capital vice of leaving in the water soluble organic matter capable of fermentation, and later, chemical agents were resorted to with the object of precipitating the soluble matter, but only incomplete results were obtained, which were slow, costly, and inapplicable on so large a scale.

We now come to the experiment which after fifteen years of study and persevering effort has given a result most complete and satisfactory. Epuration and utilization by agriculture, and filtration by spreading the sewage on permeable land have accomplished this end. It is based on simple principles, of which the demonstration is now made. All argilol-silicious and permeable soils sufficiently thick and well drained, have the property of retaining in their superior layers all the organic matter in suspension and solution contained in drain water spread on the surface of the land. It can receive without being made damp or marshy one inch of water per day, or twenty-six feet per year. It transforms the retained organic matter, rendering it capable of assimilation by plants. A very ingenious experiment just made shows this valuable property in the vegetable mould. A hollow column two metres in height was filled with earth in a manner to reproduce exactly the soil as found at Gennevilliers. Through this was passed sewage in a relative quantity to that employed in irrigation and at equal intervals with its use on the land. Epuration took place as completely as in the natural earth. Chloroform was then passed through

the column, which at once arrested epuration, and the sewage traversed the column without being purified. Paralyzation of the infusoria stopped oxidation of the organic matter. This experiment has been demonstrated by M. Schloessing, and is described in the report to the Council of Hygiene. If the surface irrigated is under cultivation the fertilizing matter is immediately utilized; if not, it accumulates without loss and transforms the poorest soil into land of extreme fertility.

A very large proportion of the water used in irrigation is evaporated either directly or by the plants in vegetation. The residuary water coming from the subsoil drains is of a remarkable purity, and does not suggest either by aspect or composition the sewage from which it proceeds. Irrigation is the most economical and efficacious means of conveying directly to the plants the fertilizing matter of sewage.

Trusting in these principles, and fortified by the works of Messrs. De Freycinet, Schloessing, Marié-Davy, and Frankland, the engineers of the municipal service have, since 1867, pursued studies and made experiments for which, notably since 1872, the council has furnished a large amount of money. These efforts have had as a result the great and actual demonstration at Gennevilliers, which evidence impresses favorably all unprejudiced persons who take the trouble to visit the lands.

After some experimental cultivation at Clichy in 1867 and 1868 the irrigation of the plains of Gennevilliers was begun in 1869 by Messrs. Mille and Durand-Claye. In 1870 and 1872 the territory comprised but a few hectares. It has increased each year, until now over 400 hectares are thus employed (about 1200 acres, which receive nearly one fourth the sewage of the city). In the beginning the water distributed was limited to a few thousand cubic metres. In 1872 444,000,000 gallons were used. In 1881 4,685,000,000 gallons were discharged on the land. In May of this year (1881) 684,300,000 gallons—22,050,000 gallons per day, or 44,100 gallons per hectare per day—these plains absorbed. In 1882, at the time of the report, the distribution reached 34,020,000 gallons per day, or 79,300 gallons per hectare, which represents a sheet of water spread over the surface equal to a little over one inch per day.

The progress, the slowness of which astonishes us now, has not been obtained without difficulty. At the origin, the engineers, relying too much on the very great permeability of the land, had not thought it necessary to establish subsoil drainage. The natural drainage, in consequence of an abundant irrigation, was found insufficient. The level of the subsoil water rose; a few cellars were flooded at Gennevilliers, and gravel quarries were inundated. This was sufficient excuse for a claim for excessive damages against so rich a victim as the city of Paris. To increase the indemnity and to compel a compromise, all possible arguments were employed. Doctor was opposed to doctor, and hygienist to statistician, when it was only a question of a few thousand francs damage to the claimants. These demands were opposed by the engineers, who in

turn were very decidedly sustained and supplied with money by the municipal council. The necessary work to insure the drainage of the plains and to remove all pretext for damages was done, and to-day the complaint is rather of the lowering of the subsoil water. Nevertheless irrigation at Gennevilliers created a prosperity until then unknown, and a time arrived when the community, frightened by the possible result of its demands and outcries,—which threatened to be the suppression of irrigation,—asked for a contract, the principal article of which was that the city should engage to continue irrigation on the plains of Gennevilliers for twelve years.

The efficacy of this system of epuration is manifest, and presents a brilliant proof. The effluent drain water has fewer micro-organisms than the water of the Seine when it enters Paris. It has the purity of spring water coming from the earth. To demonstrate the utility of the system as applied to agriculture has been slow and difficult, and not less laborious than the efficacy of epuration. For the latter the analyses made by the savants were proof beyond dispute, for the former the concurrence of the humblest practitioner; and it required time, much time.

The slowness of experiments in agriculture may be understood when we remember that to reach an end we must go through all the phases of vegetation, from the sowing of the seed to the harvest. Under our climate it is a campaign a year. If we neglect a detail, if we make a mistake at the time of sowing or planting, at the time of plowing or watering, the harvest may be a failure, and we must begin again. The difficulty was increased by local circumstances. Amongst the cultivators of land in the suburbs of Paris, no one knew the practical working of a sewage farm. One of the persistent workers who had been rewarded by success said recently that it required more than four years to acquire the necessary knowledge. To-day our cultivators are in complete possession of their art, and in the recent horticultural exhibition every one admired the remarkable products which received honorable distinctions.

In agriculture, successes which would be shown by beautiful samples obtained in the fields of experiment would be objects of curiosity. It is necessary to secure economical results, and these go far beyond the utmost expectations. For the landlord of the soil the rent value of the hectare has increased five-fold—from 90 to 450 francs. For the farmer or cultivator the prosperity has not been less. The net value of vegetable products rose from little or nothing to 4,000 francs per hectare.

In a sanitary point of view, the results have not been less satisfactory, and here again it is necessary to observe the facts on the ground. One sees a numerous population, robust and healthy in proportion to its prosperity. Its vigor assures a healthy nutrition equivalent to its works, which is the best hygiene.

As to the effects of irrigation, the same occurs at Gennevilliers, which always takes place where irrigation is practiced: from the moment it is made frequent, without stagnation, and at regular intervals, a condition which is far from favorable for the develop-

ment of paludal influences. The determining causes are eliminated; a constant activity is maintained in the vegetable life, which absorbs in its circulation all its own residues and all the organic elements placed within reach. Highly to the honor of the city of Paris be it said that, by the perseverance of its representatives, by the science and devotion of its engineers, the problem of epuration of the residues of cities and of their utilization by agriculture is absolutely and definitely solved. We have no longer the experiment of Gennevilliers; we have a system permanent and regular for the future.

The population of Gennevilliers has increased by farmers coming to occupy the lands, 34 per cent. in ten years.

Among the city documents of Paris lately presented to the city of Boston, and placed in the Public Library, may be seen photographs of the departments of this branch of the municipal service, as well as of the products of the land. The commission, in recommending the acceptance by the city of the terms which the State proposes for the extension of the work so as to include the sewage of the entire city, recommends a municipal ordinance which shall require all the water-closets in the city to be connected with the drains, and an absolute abandonment of cesspools, which now are so common in Paris. Up to the present time the city has declined to accede to the terms of the State, as they are deemed too exacting, and require a very large amount of money for the purchase of the land. The success of epuration by this method is not questioned. "The work of Babut du Maris, lately published, says "the city has just obtained 2,500 acres for the extension of the sewage farm."

The highly satisfactory operation of this system at Dantzic, where the rigorous climate of winter is as great an obstacle to overcome as here in Massachusetts, is sufficient proof that frost is not an objection to its employment on our soil. The land freezes four feet deep at Dantzic. The Vistula is frozen over from the middle of November to March, yet the temperature of the sewage at the mouth of the sewer never goes below 37° F. Irrigation is continued throughout the year with quite as much success in epuration in winter as in summer, although vegetation flourishes but four out of the twelve months.

Sewage in freezing, says Babut du Maris, eliminates its dissolved fertilizing material as thoroughly as salt water eliminates salt by the same process.

There must be abundance of land in the valley of the Blackstone, the Merrimac, and the Connecticut suitable for farms of this character. There is land bordering on Lake Cochituate well adapted to farming, for the protection of the lake from the sewage of Pegan Brook. In Arlington, Belmont, and Medford are vegetable farms favorably located, and soil well suited to this system; and before the community embarks in a scheme to build a metropolitan sewer from Natick to tide-water, which, when finished, will be of doubtful utility, judging from the experience of London, this system should be tested with the object of requiring each and every community to take care of its own sewage.

We have in the soil a chemical laboratory, a perfect filter, oxidation, vegetation, the influence of animal life and the infusoria combining to protect the sub-soil water, and so far as experience goes or chemical analyses can demonstrate, these processes of nature are amply sufficient.

We do not hesitate in covering our fields with fertilizing material where are located springs and wells. We are only solicitous lest the surface water should convey the material to them, and we raise an embankment above the level of the surrounding land, and otherwise leave to nature the protection of our drinking-water with full confidence in "*vis conservatrix nature*," and if her processes are not complete and perfect the whole world is gradually becoming saturated with filth.

STATE MEDICINE.

CHOLERA—RESEARCHES OF DR. ROBERT KOCH.

Translated from the *Courier des Etats Unis*. By S. Pollak, M.D., St. Louis.

MARSEILLES, July 10.

At a conference of physicians with Dr. Koch at the Pharo-Hospital, a careful microscopical examination was made of the microbes, which Dr. Koch brought from India.

He was asked whether he ever found the microbes in the blood. Never, was his answer. He demonstrated that the choleric microbes are half as large as the typhoid microbes, and have, besides, an oblong form. He found them in the most fulminating cases of cholera. In no other epidemic disease did he find the microbe so characteristic as in cholera. The microbe is not sporous. It is a scissiparitous product, it lives in an alkaline liquid; is destroyed by acidity, and still more by siccidity. Three hours of siccidity suffice to kill it in the dejections. Its channels of introduction are the mouth, the digestive organs, and the intestines. If it is in the air, it is soon reduced to a powder, and enters the lungs, without harm. In the intestines it multiplies rapidly.

When asked by the President of the Sanitary Commission about prophylactics, he said, that the bacilli live in water, and the virulent germ propagates itself. It can be propagated by the washing of vegetables or other aliments. The first measure which should be rigorously prescribed is to use only cooked aliments, in which the microbe cannot exist.

The treatment recommended by him in the beginning is opium, which must be discontinued as soon as the algide state is reached; stimulants may then become necessary, though he could indicate none. As soon as chilliness sets in, nothing can be done. He washes his hands in a solution of bichloride of mercury, $\frac{1}{1000}$, eats only well-cooked food, and drinks only boiled water.

Before leaving Toulon, Dr. Koch addressed the following communication to the Council of Hygiene:

Cholera propagates itself in assemblages of men; its principle is unexceptionally communicated by direct contact with men, or with their wearing apparel.

In cholera times, a well-regulated life must be led;

experience has demonstrated that troubles of digestion favor an attack of cholera. Excesses in eating and drinking, the use of heavy, indigestible food, must be avoided, and also anything which may cause diarrhoea. A physician should be called in immediately. Never absorb anything which comes from a contaminated source; when in doubt whence it came, subject it to a thorough cooking, and especially so milk.

Water tainted by human detritus is forbidden; avoid the use of doubtful water, of water drawn from shallow wells or a swamp, a pond, or from a creek receiving vitiated water. Consider as essentially dangerous water which has been in any manner soiled by choleric dejections. Water which has been used for rinsing vessels, or washing of clothing, should not be poured into a well or into a running stream. It is impossible to get absolutely pure water, the simplest way is therefore to have it boiled.

These observations refer not only to water used for drinking, but to water used in the household; for the choleric germ, once existing in the water, can be communicated to all who make use of it, whether in the laundry, scullery, kitchen or bath. The most important consequences of these remarks are, that it is not sufficient to guard against cholera, to use pure, or even boiled water.

One case of cholera can become the focus of an epidemic, hence cholera patients should be removed from contact with all those not absolutely necessary to take care of them.

Public assemblages, fairs, fetes, should be avoided. Never eat or drink in a room where the choleric are; their dejections should be collected in vessels containing a phenic solution.

All objects soiled by the dejections should be cleansed with dry cloths, which have to be burned immediately. Apartments which have been occupied by the choleric should remain vacant for six days.

Persons who are brought in contact with cholera patients, should wash their hands with soap and phenic acid, or solution of bichloride of mercury $\frac{1}{100}$. Cadavers should be removed immediately, and the funerals should be simplicity itself. The cortege should not enter the mortuary house, and none of the objects belonging to the choleric should be removed without having been previously disinfected.

Laundresses should not receive the linen coming from a choleric, without having undergone thorough disinfection.

OPACITIES OF THE CORNEA.—Dr. Michel recommends sulphate of cadmium, of the strength of two and a half grains to the ounce of mucilage, as an application to opacities of the cornea. A camel's-hair brush, dipped in this wash, is applied to the centre of the spot and retained in contact with it for a few seconds. At first the application is made once a day, but after a while is repeated two or three times in the twenty-four hours. When the pain grows less, the strength of the solution may be increased to five grains or even seven grains to the ounce. When the opacity is of recent formation it readily disappears under this treatment, but when it is of old date the applications must be long continued. (*Practitioner*, Jan., p. 53.)

BOOK REVIEWS.

THEORY AND PRACTICE OF MEDICINE. BY FREDERICK T. ROBERTS, M.D. Illustrated. Fifth American Edition. Publishers, P. Blakiston, Son & Co.

This work is so well known to American Medical men that an extended notice of it is superfluous. The present edition consists of a single volume of a thousand pages. Numerous additions have been made to the subject matter in order to incorporate the most recent discoveries. The characteristics of the work are fullness without prolixity. The work is, as it always has been, an excellent manual.

FOREIGN CORRESPONDENCE.

LONDON LETTER.

THE PATENT MEDICINE STAMP ACT—THE ENGLISH BOARD OF INLAND REVENUE DECISION AGAINST NOSTRUMS, SPECIFICS, AND LEGITIMATE FOREIGN DRUGS.

LONDON, July 14, 1884.

The recent decision of the Board of Inland Revenue against legitimate foreign drugs, as well as all patent medicine, has caused great dissatisfaction among both the medical and pharmaceutical professions throughout the Kingdom. It appears that the action of the Board was made specially upon the medicinal preparations of Park, Davis & Co., many of which are now being largely used in GREAT Britain. The Stamp Act of 1812, which has thus been unjustly interpreted by the board against the profession of this country, was in vogue when both pharmacy and medicine were in their infancy. English pharmacists and physicians no longer depend upon their own home products for fine preparations and good therapeutic results, but upon the valued remedies obtained from all parts of the world. In other words, the great strides of these two professions in England have outgrown this obsolete Stamp Act, and the decision recently rendered has caused universal regret. In fact, the English physicians and pharmacists are most liberal in all matters that concern their respective departments. They are anxious—in truth, enthusiastic—to test the merits of all preparations that may come from any nation on the earth, and especially desirous of using American drugs. During my short stay in London, in visiting the various hospitals, I have been most agreeably surprised to find the large quantity of American and other foreign drugs that are in constant use in these institutions. The therapeutists connected with these hospitals, who are ranked as the best and most scientific in the world, are the most liberal and progressive in their opinions. For instance, the collection of drugs used by Dr. William Murrell, one of the most prominent teachers of *Materia Medica* and Therapeutics at the Westminster School, includes all the

recent preparations, both simple and compound, found in use at the present day. There was convallamarin and all the other important alkaloids, and jequirity, and even a full line of those useful and practical remedies, the oleates, that have been introduced and so largely manufactured by Dr. Lawrence Wolff, the chemist, of Philadelphia. A full line of foreign drugs are not used alone in the institution just named, but in all the schools in this great European medical centre. It can therefore be clearly seen what a great inconvenience and dissatisfaction the recent decision of the Board of Inland Revenue will create. It will limit the usefulness of therapeutics in the United Kingdom. This increase of price on legitimate foreign drugs by the patent-medicine Stamp act will place them, in the great majority of cases in practice, beyond general use by practitioners for their patients. English physicians are practical in all matters, and they always study economy for the sake of those they serve so well. This unfortunate Stamp act has, however, operated largely in favor of patent medicines ever since it has been in existence. Thus, the government stamps officially all worthless trash, and the gullible public are impressed with the conviction that the drug so highly endorsed must be good, pure, and perfect. The most ingenious, as well as poisonous combinations are thus easily, under the protection of the government, dispensed without a word of caution to the people. I am pleased, however, to see that the profession are awake to the needs of the times, and are actively pushing a bill before Parliament which will eradicate all the abuses of this act. The bill has a very large support, and the profession are all convinced that it will soon pass and become a law that will benefit the people directly. S.

DOMESTIC CORRESPONDENCE.

BOSTON LETTER.

The Annual Meeting of the Massachusetts Medical Society for the current year, constituting the one hundred and third (103) anniversary, was held in Boston, June 10 and 11. The number of members present was unusually large, and there was a great amount of interest in the proceedings of the meeting. The weather was fine. The arrangements for the meeting were admirably conducted by a strong committee consisting of six of the most energetic, public-spirited of the younger physicians of Boston, aided by the hearty coöperation of a large corps of able and willing assistants.

The anniversary exercises were inaugurated by an invitation to the Fellows of the Society to visit and inspect the Massachusetts General Hospital, the City Hospital, the new Children's Hospital, and the Lying-in Hospital. These institutions were the object of attention on the part of many of the Society until 12 o'clock, when the larger number of delegates assembled in the spacious hall of the new Harvard Medical School to listen to the address of Prof. H. P. Bow-

ditch on "Methods of Instruction and Research in Physiology with Demonstrations." The address was of great interest, and portrayed and illustrated the vast advances which have been made in the science of Physiology and in the modes of teaching, whereby laboratory experiments and absolute demonstrations have replaced to a great extent the tiresome didactic lectures of a few years ago. During the essay various experiments illustrative of the methods employed in physiological research were performed before the audience to their great satisfaction.

Dr. Thos. Dwight, Professor of Anatomy, also gave a lecture and demonstration illustrative of the improvements which have been devised both for the didactic and for the experimental teaching of this important branch of the medical art, and the Fellows of the Society were shown the manner in which the dissection of subjects has been so influenced by modern hygiene, that even this most repulsive part of a student's curriculum has been made tolerable, if not attractive. The demonstrations of anatomy for which Prof. Dwight is justly celebrated were very interesting and the Society testified its appreciation of their practical character and artistic execution. At 3 p. m. Dr. Geo. W. Gay, Surgeon to the Boston City Hospital, described the "Peuster Posterior Splint in Fractures of the Leg" and made a practical application of the splint to a patient before the audience. An extended description of this apparatus is deferred at this time, as it is hoped that a full report of Dr. Gay's paper with illustrations may soon appear, which will be forwarded to the JOURNAL as early as possible. Any further attempt to do justice to the subject at this time would extend this letter to an unwarrantable length.

An adjourned meeting of the Society was held at 4 o'clock, for the transaction of business, and this proved to be the most exciting event in the entire list of anniversary exercises. In order to be understood it will be necessary to refer to a similar meeting held two years ago for the same general purposes. At that time the office of President of the Society was held by Dr. H. W. Williams, one of the most prominent members of the profession in New England, a gentleman whose uniform suavity of manner and courtesy of bearing, combined with a dignified presence, concealed and masked a firmness of character and a pertinacity of disposition which in any other man would have seemed like obstinacy. On the occasion mentioned, in 1882, the subject of the eligibility of women for and their admission to the rights and privileges of the State Society was brought before the meeting. The same subject had been touched upon once or twice previously at the annual meetings of the Society, but had been easily disposed of on each occasion. The disorder had, however, become gradually more and more extended, and each year a larger number of members had become infected with heresy until now the movement had acquired a dangerous importance. At the annual meeting in 1882, the subject was therefore formally introduced and brought before the meeting for discussion. There was an evident feeling that the measure would be adopted by the Society, and the friends

of the good old principles of the profession which have been fostered by the Society for more than a century trembled at the proximity of the ballot which they saw would demolish their idol of conservatism at one fell blow.

It was at this supreme moment that the then President of the Society, Dr. Williams, executed a stroke of genius in chairmanship which won for him the plaudits of the sympathizers and achieved again a victory for the conservative element of the Society. When the danger was most imminent, when the offensive doctrine had found shape and voice and had been presented to the meeting in the classical form of a motion, then the chairman ruled the motion out of order on the ground that by a strained reading of one clause of the By-laws of the Society, the Board of Councillors and the Society at large must conjointly ratify any amendment to the organic laws of the Society before these laws can be changed. By the reading of the clause in question, the chairman claimed that it appeared that the Councillors must take the initiation, and the society was powerless to originate a motion to amend its own By-laws; but was subject to the pleasure of a Board of Councillors which the Society had itself created. To the more ardent and impetuous members of the Society, especial among the younger men, this step looked like an attempt to muzzle the Society, and to virtually establish a ring rule which would entirely subvert any voluntary expression or action on the part of the general Society. Some impulsive spirit ventured at this time to appeal from the decision of the chair, and after a spirited debate the decision of the chair on that occasion was sustained by a bare majority. This action placed the troublesome question of the admission of women at rest for the time being. Last year it showed but a slight degree of recuperation, but like Banquo's ghost it stalked into the meeting of this year in all its hideousness and would not be banished. The large attendance, the growing conviction that the threatened measure was sooner or later an inevitable issue, coupled with the fact that a certain amount of work had been done by a self-appointed committee looking to this object, all conspired to render the subject a more formidable one this year than ever before. As may be imagined, the friends and the enemies of the measure were present in full force.

The meeting had hardly been called to order and the records of the previous meeting been read, when the venerable Dr. Henry I. Bowditch arose, and in a clear, ringing voice, moved the proposed amendment to the By-laws of the Society, which reads as follows: "Candidates for admission to the Massachusetts Medical Society may be male or female, and must by proper credentials and examination satisfy the censors of said Society that they possess the following qualifications for fellowship" * * * etc.

The motion was seconded, and was ably advocated by its friends, and vigorously opposed by its foes, and finally the question was called for.

The President of the Society, Dr. A. Hosmer, immediately fell back upon the precedent established by his illustrious predecessor of two years ago, and promptly ruled the motion out of order. A scene of

wildest disorder at once ensued, in which the decision of the chair was appealed from in twenty directions at once, and speakers were vainly endeavoring to make themselves heard in all parts of the hall. Amid much confusion, a motion to reconsider the vote of two years ago was presented, and seconded and debated. The question was called for and was again summarily ruled to be out of order by the chairman. Again the decision of the chair was appealed from, and for a time it was quite impossible for the chairman to control the meeting.

At length, when quiet was in some degree restored, and the ridiculous position of affairs became apparent, there being two motions before the house, neither of which had been put, and two rulings of the chair, both of which had been appealed from, the chairman at length seemed to perceive that it was impossible to further prevent or pervert the natural course of events in parliamentary proceedings, and the questions were accordingly taken up *seriatim*. First, the appeal from the ruling of the chair that the motion of Dr. Bowditch was out of order, was decided by a large majority against the chairman. The original motion of Dr. Bowditch was again put, and declared lost. The vote was doubted, a standing vote was demanded, which gave a majority of about 75 for the amendment. A committee consisting of Dr. Henry I. Bowditch and Dr. Morrill Wyman was appointed to report the action of the general Society to the councillors at their meeting in the evening, and to move its passage in that body. Here, also, a last determined resistance was made to the passage of the vote, but after a lengthy debate it was adopted by the Council, and to-day for the first time in the history of the Massachusetts Medical Society, woman is accounted equally eligible with man for fellowship in its rights and its privileges.

On the following day, June 10, the annual reports of the Society were presented, the names of those removed by death, and of those added to the Society, were read, and the announcement was made that the membership was increased to about fifty more than its roll one year ago.

A paper was read by Dr. F. Nickerson, of Lowell, on "A Case of Chylous Deposit in the Abdomen." Dr. L. Huntress, of Lowell, read a paper on "The Pitch of Percussion Sounds," which was followed by a debate in which Drs. Henry I. Bowditch, G. M. Garland, and others, took part. Dr. J. F. A. Adams read an interesting essay on "Sanitary Forest-Culture," which was followed by an animated debate, in which Drs. H. O. Marcy, Albert N. Blodgett, and others, took part. At the conclusion of the discussion, the subject of forest-culture was referred to the Committee on Legislation of the Society, and by unanimous vote the name of Dr. Adams was added to that committee, which was instructed to endeavor by all proper means to secure such legislative enactments as may be necessary to check the wholesale destruction of the forests in our country, which will otherwise soon experience a famine of wood and lumber; and to call public attention to the sanitary influence of forest trees and timber lands upon the inhabitants. Dr. Blodgett called especial attention

to the efforts made in foreign lands to cultivate forest trees and to reproduce timber in districts adapted to its culture, as well as the strict regulations observed in the destruction of forests or individual trees, even on private domain.

Dr. J. Seaverns, of Roxbury, then presented an essay on "Weight as an Indication of the Character of Risks for Life Insurance." This was a study of the mortality in a series of about 300 cases of death occurring in the membership of a coöperative Life Insurance Company, divided into groups varying in the ratio of 15 per cent. and 25 per cent. both above and below the normal standard from age and height, as established in the well-known mortality tables of the insurance companies.

At twelve o'clock the annual oration was delivered by Dr. John Crowell, of Haverhill, and at one o'clock the Society walked in procession by seniority to the skating rink, where the Annual Dinner was served.

After ample justice had been rendered to the repast, the Anniversary Chairman, Dr. Geo. B. Shattuck, arose, and in a few felicitous words introduced the President of the Society for the ensuing year, Dr. Chas. D. Homans, of Boston, who was greeted with cordial applause.

The retiring President was then called upon and spoke at some length of the history of the Society, its powerful influence for good, its endeavors to sustain the dignity and integrity of the profession, and its promises for the future.

The Governor of the Commonwealth, His Excellency, Hon. Geo. D. Robinson, was now introduced by the chairman, and for nearly half an hour held the Society spellbound by his eloquence. He touched upon many of the important relations which the profession of medicine maintains toward the public, the system of health inspection, the powers and province of State and local Boards of Health; the practical working of the system of Medical Examiners introduced some years ago; and suggestions for the future development and usefulness of this important department of public medicine. His Excellency could not refrain from congratulating the Society on its action of yesterday in admitting women to its fellowship, and expressed the opinion that the result to the public, to the profession, and to the women themselves would be only for good. Remarks were made by representatives of the sister professions, theology and the law, all uniting in congratulating the Society upon its increasing prosperity and the ever extending influence which it is gaining upon the public through its beneficent ministrations.

At about 4 o'clock the Society adjourned.

Looking back upon the anniversary just past, by far the most striking feature in its deliberations is the action by which the doors of the Society have been opened to women. This event will be looked upon by the friends of the measure as the beginning of a new epoch in the annals of the Society, and can be compared in magnitude only with another memorable action by the Society about fifteen years ago, when it expelled a portion of its body as unfit for longer membership on account of supposed inclina-

tions toward homœopathy. This measure engendered much rancor at the time both within and without the Society, and is now very generally regarded as a stupendous mistake. Whether in a few years the members of the Society will look back with similar misgivings on their action in regard to *women* is a question. From private sources it is learned that steps have been already taken by some of the women here engaged in practice, to obtain admission to the Society, but this consummation is still far from a reality at present on account of certain prohibitory enactments in the standing resolves of the Councillors, prohibiting their admission to examinations by the censors of the Society, one resolution even providing for the legal defence of the censors in case of judicial proceedings on account of a refusal to examine female candidates for fellowship. By what means or at what time these disabilities and restrictions will be removed by the Board of Councillors remains to be seen. The champions of the women feel that they have achieved a brilliant victory, and assert that the triumphant entrance of the gentler sex into the full membership of the Society will be speedily accomplished, while many grave and decorous physicians are hoping and praying (I think they pray) that the Councillors by their deliberate and conservative methods may still avert the dreaded amalgamation for some time yet.

EDITOR OF JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION.

The following has already appeared in several American as well as European journals, and among the number may be mentioned the *Medical Press* and *Circular*:

LACK OF REFINEMENT IN THE AMERICAN MEDICAL ASSOCIATION.—A resident of Washington writes to the New York *Medical Journal* as follows: "The usual disgraceful performances took place at the receptions. Mrs. L—— generously opened her beautiful house, and provided as fine a table as Demenet could serve. She was rewarded by having men stalk in (hats on their heads) from the front room to the dining-room, where they fought like wolves for places at the tables, overturning piles of plates, breaking her expensive ornaments, and soiling her rugs with pools of tobacco-juice."

The author of this slander will, in all probability, never be known, excepting to the editor of the New York *Medical Journal*, who appears to have given it circulation without attaching the name of its puerile Washington correspondent.

I have the facts in my possession from the highest authority on this question that: "*The guests were most courteous and civil.*"

J. F. JENKINS, M.D.

Tecumseh, Mich., July 28, 1884.

HEADACHE.—*Menthol*.—This drug has never failed to relieve my own headache, or any nervous headache in my care. I simply wet the finger with the following mixture, and pass it several times over the forehead: *R.* Menthol, 3j; alcohol, 3j; olei caryophylli, olei cinnam., āā ℥xx. M. (Dr. F. O. Lockwood, Therapeutic, Gazette, Oct., 1883.)

MISCELLANEOUS.

OFFICIAL NOTICE.

ANNUAL DUES from members of the Association—*Five Dollars* per annum—are payable directly to the Treasurer. Such payment entitles them to receive the *JOURNAL* of the Association for one year.

SUBSCRIPTIONS TO THE *JOURNAL* from those who are not members should be forwarded to the office of publication, Chicago.

BACK VOLUMES OF THE *TRANSACTIONS* may be procured, at reduced rates, by addressing the Treasurer.

THE *INDEX* to the 33 Volumes of *Transactions* will be forwarded, postpaid, on receipt of *One Dollar* by the Treasurer.

According to a resolution passed May 9, 1884, at the Washington meeting, continuous payment of Annual Dues is required, to retain permanent membership.

RICHARD J. DUNGLISON, M.D.,
Treasurer.

Lock Box 1274, Philadelphia, Pa.

TO ADVERTISERS.

The quality and extent of the circulation of the *JOURNAL* OF THE AMERICAN MEDICAL ASSOCIATION render it an exceptionally valuable means of communicating with a large and select portion of the medical profession of America.

The value of advertisements in the *JOURNAL* is enhanced by the exclusion of all of questionable character.

Copy received until Monday. A copy of the *JOURNAL* is sent free to advertisers.

For rates, etc., address,

G. P. ENGELHARD & Co.,
Sole Agents Advertising Department, *JOURNAL* OF
THE AMERICAN MEDICAL ASSOCIATION,
69 Dearborn St.,
Chicago, Ill.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT UNITED STATES ARMY, FROM JULY 19, 1884, TO JULY 25, 1884.

Wright, J. P., Major and Surgeon, assigned to duty as Post Surgeon, San Antonio, Texas. (By per. 4 S. O. 87, Hdqrs. D. of Texas, July 14, '84).

Wright, J. P., Major and Surgeon, granted leave of absence for one month, on surgeon's certificate of disability. (Par. 3 S. O. 89, Hdqrs. D. of Texas, July 17, '84).

Hartsuff, Albert, Major and Surgeon, leave of absence extended one month. (5. O. 79, Hdqrs. Div. of the Mo., July 18, '84).

Strong, Norton, 1st. Lieut. and Asst. Surgeon, granted leave of absence for two months, to take effect when relieved from duty in Dept. of the Platte. (Par. 2 S. O. 68, Hdqrs. Div. of the Mo., June 27, '84.)

OFFICERS OF
THE AMERICAN MEDICAL ASSOCIATION
 AND OF ITS SEVERAL SECTIONS, 1884-5.

PRESIDENT.

H. F. CAMPBELL, of Augusta, Georgia.

FIRST VICE-PRESIDENT.

J. S. Lynch, of Maryland.

THIRD VICE-PRESIDENT.

J. W. Parsons, of New Hampshire.

PERMANENT SECRETARY.

Wm. B. Atkinson, 1400 Pine St., Philadelphia.

SECOND VICE-PRESIDENT.

S. D. Mercer, of Nebraska.

FOURTH VICE-PRESIDENT.

H. C. Ghent, of Texas.

TREASURER.R. J. Dunglison, ^{Lock Box} 1274, P. O. Philadelphia.**LIBRARIAN.**

C. H. A. Kleinschmidt, Washington, D. C.

Place of meeting, 1885, New Orleans, La.; Time of holding meeting, last Tuesday in April.

COMMITTEE OF ARRANGEMENTS.

Samuel D. Logan, Chairman; S. E. Chaillè, E. S. Lewis, Joseph T. Scott, W. G. Austin, W. H. Watkins, J. P. Davidson, J. A. G. Fisher, Geo. W. Lewis, B. A. Pope, W. C. Wilson, M. Schuppert, Geo. J. Friedrichs, F. Loeber, D. Jamison, G. K. Pratt, L. F. Salomon, J. H. Bemiss, Geo. Lawrason, C. U. Gaudet, Sam'l M. Bemiss, C. J. Bickham, Chas. Turpin, Jno. Carter, A. W. DeRoaldes, S. S. Herrick, W. S. Mitchell, E. T. Shepard, E. Souchon, T. D. Layton, T. S. Dabney, S. R. Olliphant, Edward Harrison, A. B. Miles, Joseph Holt, P. B. McCutcheon, F. H. Parham, G. B. Underhill, Stanhope Jones, E. Chassaignac, J. Dell'Orto.

ASSISTANT SECRETARY.

W. H. Watkins, New Orleans, Louisiana.

BOARD OF TRUSTEES FOR JOURNALIZING THE TRANSACTIONS.

J. M. Toner, Washington, D. C., President;
 E. M. Moore, Rochester, N. Y.; Leartus Connor, Detroit, Mich.;
 J. H. Packard, Philadelphia;
 H. F. Campbell, Augusta, Ga.; A. Garcelon, Lewiston, Me.;
 P. O. Hooper, Little Rock, Ark.;
 L. S. McMurtry, Danville, Ky.; J. H. Hollister, Chicago, Ill., Secretary.

OFFICERS OF THE SECTIONS:

"Practice of Medicine."

Chairman—H. Didama, Syracuse, N. Y.; Secretary—G. M. Garland, Boston, Mass.

"Obstetrics and Diseases of Women."

Chairman—R. S. Sutton, Pittsburgh, Pa.; Secretary—J. T. Jelks, Hot Springs, Ark.

"Surgery and Anatomy."

Chairman—Duncan Eve, Nashville, Tenn.; Secretary—E. B. King, Allegheny, Pa.

"Ophthalmology, Otology and Laryngology."

Chairman—J. A. White, Richmond, Va.; Secretary—Eugene Smith, Detroit, Mich.

"Diseases of Children."

Chairman—J. H. Pope, Marshall, Texas; Secretary—S. S. Adams, Washington, D. C.

"Oral and Dental Surgery."

Chairman—W. W. Allport, Chicago, Ill.; Secretary—E. C. Briggs, Boston, Mass.

"State Medicine."

Chairman—E. W. Schaufler, Kansas City, Mo.; Sec'y—J. N. McCormick, Bowling Green, Ky.

Committee on "Necrology."

Chairman—J. M. Toner, Washington, D. C.

ORIGINAL ARTICLES.

ON THE CLINICAL STUDY OF EPILEPSY.

BY WM. PEPPER, M.D., OF PHILADELPHIA, PA.

Read in the Section on Practice of Medicine and Materia Medica of the American Medical Association, May, 1884.

MR. CHAIRMAN:—When the eminent President of this Association, seconded by yourself, asked me to prepare some remarks for opening a discussion before the Section on Medicine, I felt that the desire was not so much that I should give a formal paper, as it was that I should bring before the body some subject of general interest, and one in which all could take part.

The subject of chronic convulsive affections, grouped under the name of epilepsy, is one of such large medical and social importance, that I felt that I could not do better than select it, large and vague as it is. In what I say, I shall simply bring before the Section the notes of a few cases from my case books, and make them the subject of brief practical comments as I pass along.

The conception that I think we must form of epilepsy, is a very broad one. For studying the disease to the best advantage, if we could entirely exclude cases where any anatomical change has occurred, it were desirable. While it is perfectly possible to do this in cases where definite symptoms of cerebral tumor are associated with convulsions, and where we recognize that the attacks are purely symptomatic, there are many cases which we have to call epilepsy, where doubtless there are minute changes in the meninges or in the motor centres of the cortex, undistinguished by other symptoms. Prominent among these are the cases of epilepsy following sunstroke, of which I shall give illustrations later.

But there may be difficulty, even when a distinct history of traumatism exists, and unquestionably, if autopsies could be secured in every instance, it would be found that all collected series of cases of epilepsy which have served as the basis of statistical calculation, contain many cases of purely symptomatic epileptiform character. The following is quoted, partly as an illustration of these remarks:

CASE I.—*Epileptic Attacks following Injury to Head, Recurring after long Interval of Immunity. Abscess in Anterior Lobe of each Hemisphere.*

Dr. O. A. R., age 44 at the time of his death; married; excellent habits, and without hereditary predisposition. At the age of 23 was thrown out of his wagon, striking his head against a tree, producing a depression of the frontal bone to the right of the median line, over the frontal sinus. He had convulsions at the time, but recovered perfectly, continued his practice successfully and served as an army surgeon very creditably, and had no convulsions, nor any cerebral symptoms whatever, for 18 years, until August, 1881, after which time he had severe convulsions at intervals from four to six weeks. There was no albuminuria. No cardiac disease. No symptoms of pressure, nor any sensations referred to the spot of injury. The recurrence of the convulsions seemed to be connected with sustained mental anxiety and worry and the effects of continued hard work, as he had no vacation for 16 years. Ophthalmoscopic examination gave negative results. Bromides failed to influence the spells. The actual cautery was applied to the neck, and a strict diet was ordered, with cessation from work. There was marked temporary improvement, the intervals between the attacks being increased to six months. He then became so much better that he insisted upon resuming practice, when immediately violent convulsions occurred, which were uninfluenced by any measure. Trephining was at last performed by Dr. Agnew at my request, when slight depression of the internal table, with a fissure and displacement inward of a minute spicula of bone were found, with an old abscess of considerable size in the anterior lobe of the right hemisphere, and a small abscess in the anterior lobe of the left side. There can be little doubt that a slow irritative lesion had existed all these years, and the brain became habituated to its presence, and it was not until a large area and overwork established convulsions, which thenceforth were uncontrollable.

Equally difficult and yet important is it to recognize and eliminate all instances of hysteria. In typical cases of hysterio-epilepsy, such as the following, this is readily done.

CASE II.—*Hystero-Epilepsy, Consequent on Membranous Enteritis.*

Mrs. McC., age 30. Several of her family have presented nervous symptoms, neurasthenia, etc. She herself was in perfect health until, after over-exertion nursing a relative, she was seized with severe dysentery, which passed into a subacute form and has been followed by membranous enteritis, continuing now for more than eight years. The membranous formations are peculiarly numerous, long, thick and firm.

Gradually a condition of marked neurasthenia developed, with excessive mobility of the system, and in the course of two years decided hysterical tendency showed itself. She became easily moved to tears, although her usual state remains one of great animation and cheerfulness. Excessive spinal tenderness was developed and, indeed, the entire body has become morbidly sensitive. Attacks of hystero-epilepsy first appeared five years ago, and still continue, though less frequent and severe than formerly. They are very characteristic and interesting, and can be induced at will by pressure on the spine or over the ovaries; also by fatigue or excitement, and are most common at the menstrual period. Ovarian compression will not check them. There is no erotic manifestation. Her character remains frank, generous, self-sacrificing and courageous. General nutrition has been well preserved. Menstruation is regular, but scanty and somewhat difficult. Obstinate constipation, connected with atony of the lower bowel, is a chronic condition. Prior to the passage of a membrane the general hyperæsthesia is exaggerated, great abdominal distress exists, and crops of from four to twelve dark-bluish stigmata appear on different parts of the body, chiefly on the legs and thighs. These spots look like bruises, are often a half inch in diameter, and persist for five to twenty days, gradually fading and changing color as when a bruise is passing away. At such times the convulsive attacks are frequent. Bromide has done no good. No remedy, either by the mouth or rectum, has cured the membranous formations. Repeated application of the actual cautery at different parts of the body has been made, and each time with marked and somewhat enduring good results; and repeated changes of scene, and wholesome, cheerful influences, have had an excellent effect.

Contrary to the teachings of Charcot, my own experience would be that in the cases of hystero-epilepsy seen in this country, compression of the ovaries does not arrest the attack, nor are erotic manifestations prominent. In this respect the disease as it occurs in this country and in England, is in marked contrast with the disease as it is said to occur in France, particularly in hospital patients.

While such cases as the above are easily distinguished, there are many others where the convulsions occur in such manner, and exhibit such coördinated movements, as to render it difficult to say whether they are hysterical or epileptic. Indeed, I think that it must be conceded that there are cases of epilepsy and hysteria combined. In both of these affections, we must undoubtedly recognize some rooted morbid sensibility and instability of nerve-tissue, probably distinct in its seat in these two affections. In epilepsy it would seem that there is a supremely unstable condition of one or more areas, minute or extensive, of the gray matter within the encephalon, rendering it liable to sudden and violent discharges which it may possibly be that in hysteria, in hystero-epilepsy and in the combined forms to which I have alluded, it is the ganglionic nerve centres which are in this unstable condition. Instability of the encephalic gray matter may co-exist, so that an attack may be

induced through violent disturbance of the ganglia controlling intracranial circulation, with consequent discharge from an unstable centre in cortex or elsewhere.

Without entering farther on this abstruse question, the nervous instability which must be recognized as the fundamental element, is brought about in various ways. The influence of heredity is so well known that no further allusion to it is necessary. The effects of nervous exhaustion as from overgrowth, over-strain or exhausting illness has long been recognized. The exhaustion which follows typhoid fever, furnishes a good example of the influence of this factor, as in the following case:

CASE III.—*Epilepsy following Typhoid Fever.*

Mrs. B., age 38, had been in good health until five years ago when she had a very severe attack of typhoid fever. This was complicated with hemorrhages, phlegmasia alba dolens of both legs, and a relapse of the fever kept her in bed four months. On the first occasion of going out to walk after the fever she fell in severe convulsions of epileptic character, with tongue biting. This was the first convulsion she had presented. For three years subsequently, convulsions of an epileptic character continued to recur at varying intervals, sometimes as frequent as twice a week and of severe and typical character. They were often induced by exertion in the sunlight or by sudden exposure to very bright light. Gradually, as her health improved, the attacks became less severe and less frequent. For the last twelve months she has had no general convulsions but has merely had minor attacks with momentary unconsciousness preceded by sharp præcordial pain; at increasingly long intervals.

In the same way epilepsy frequently develops after scarlet fever, but in reference to the relation of epilepsy and scarlet fever, I shall speak more fully, later. Shock to the nervous system, whether this be purely psychical, as from fright; or whether it be from such influences as exposure to the violent action of the sun; or, whether it has been connected with an actual injury, with or without distinct lesion of the cranial bones, frequently appears as the exciting cause of the disease. I have already alluded to the great frequency with which heat-exhaustion, or actual sun-stroke, figures in this relation, and the following case is quoted partly to illustrate this, and partly with reference to certain points of treatment.

CASE IV. Mr. G. W. W. His mother has borne a number of healthy children, but is herself, at the menopause, highly anæmic and neurasthenic with tendency to asthma. He is 29 years old, and has been subject to severe sick headaches from boyhood. Four years ago, while working on a raft, was overcome by the heat and was attacked with violent headache and nausea, loss of consciousness and afterwards had fever with delirium. His general health was much impaired, and in addition during the next eighteen months, he had six severe attacks and a number of minor attacks. The severe attacks began with convulsive pain in the left side of the head, about the left mastoid region, increasing in intensity

until it became unendurable in from two to five minutes, and he then became unconscious. In the minor attacks the pain would be on the right side of the head and around the right eye, and increase until he goes into a stupor and becomes almost, if not quite, unconscious, and afterwards passes into a heavy sleep for hours. The severe attacks are preceded by confusion of vision, objects look blurred, move and close in upon him until all gets dark. This takes twelve or fifteen minutes, then the speech becomes affected; he thinks of objects he wishes to mention, but calls them by the wrong name, this increases until he cannot speak at all, though his tongue is not paralyzed. These changes are going on during the latter part of the vision changes, and reach their height about the same time, and then a numbness or tingling begins in the left biceps extending down to the hand and left side to the foot. The left side feels cold and numb and tingles, and he then loses power of moving left arm or leg, though he can still move right members freely. This is the last he remembers. He is usually able to reach some place to lie down. After this there are convulsive movements with tongue biting, and very excited action of the heart. The urine is normal. No cardiac murmur, but heart's action easily excited.

When I first saw him in 1882, there was marked tenderness over the left suboccipital nerve behind the mastoid process where the pains begin at the attack.

There has been great excess in sexual intercourse, which had probably aided in producing his constitutional susceptibility. Bromides and repeated blisters failed to produce marked effect. The actual cautery was applied February 8, 1882, and the effect of this, with care in diet and avoidance of severe exercise or much exposure to the sun, were followed by immunity until the summer of 1883, when he began to expose himself too much and to have headache; and in September, while driving in the hot sun, he had an attack beginning with flashes of light, sense of surrounding objects drawing in on him, though he was able to guide his horse home and reached his room, where he broke three capsules of nitrite of amyl, which did not prevent the attack from going on to complete unconsciousness and convulsions, followed by stupor for three hours.

Renewed application of cautery was again made, and restriction of habits has been insisted upon, and he is again improving. The beneficial effects of the cautery, and avoidance of exertion, was very marked here for many months, in the absence of both minor and major attacks, as well as of headache and uncomfortable sensations about the head.

Again, instability of the circulation with associated disturbance of the nutrition of the brain, as in heart disease, anæmia, etc. plays an important part as a predisposing cause in many cases. And I would call especial attention to the remarkable frequency with which careful physical examination will show the existence of organic cardiac disease in cases of epilepsy. In this connection allusion is also to be made to the possibility of minute capillary embolisms and interference with the nutrition of small areas of the brain in cases of valvular disease of the heart. Prolonged

peripheral irritation may gradually bring about this instability and establish the habit of convulsive seizures. This peripheral irritation may be from prolonged morbid dentition, from severe and protracted genital irritation, or from long continued gastro-intestinal irritation, especially in the form of chronic catarrhal irritation of the mucous membrane with the resulting anæmia and malnutrition.

Such general considerations help us to realize the condition of those whom we group under the name of epileptics, and I think show us that they are not affected by a single definite disease, presenting a vast variety of type and severity, but that they exhibit in common, merely a state of impaired nutrition and of morbid instability of the gray matter within the encephalon, however induced or maintained and varying in degree to an immense extent in different cases, and thus rendering them liable to explosive discharges or convulsions upon provocations of correspondingly varying intensity. There are in all probability cases where progressive minute molecular changes in the nervous tissue induce the outbreaks at certain irregular periods. Such may be the cases of recurring status epilepticus with elevated temperature, and followed each time by evidences of advancing deterioration and also such cases as exhibit distinct progressive impairment of cerebral function. Such convulsions may then be as truly symptomatic as in the case of intracranial tumor. But far more commonly the irregularly recurring convulsions are connected with not an advancing morbid tendency, nor an irregularly progressive anatomical change, but with the occasional and irregular operation of those widely different causes which in different cases are calculated to disturb the weak centre and induce the explosive discharge. Unquestionably, it is true that the evil effects of habit are seen here as prominently as in other chronic conditions, and if the tendency or instability can not be reduced and the provoking causes be avoided, then the mere continuance of the attacks induced by such provocations will develop a more and more facile response on the part of the weak centres until at last attacks may be induced by almost imperceptible causes.

It is important to recognize the degree of this instability in each case, and to recognize that we are not dealing with a radical morbid condition, but merely with an exaggeration of the normal condition. Every one is liable to convulsions: it is merely a question of the provoking cause required. Take the following case of single convulsive seizure in an adult consequent upon intense dental irritation:

CASE V.—*Single convulsion, induced by intense pain.*

Mr. — 25 years old, with gouty diathesis, plethoric and somewhat intemperate in habits. Was seen in 1879, after he had a violent convulsion with tongue biting, followed by confusion of mind for several hours. It had been preceded by violent toothache lasting 36 hours, preventing sleep or eating, and finally becoming so severe that he felt he was losing his self-control, which is the last he can recollect. No subsequent spell has occurred.

Or the following case where alcoholic excesses induced the convulsions:

CASE VI.—*Epileptic convulsions apparently induced by Alcohol.*

W. J. F., age 45, had drunk whiskey to excess and used tobacco to excess. Had primary syphilis 25 years ago followed by no constitutional symptoms. His general health was excellent until 5 years ago when he began to have attacks of acute dyspepsia following his hard drinking. Hemorrhoids ensued which were operated upon, and five weeks afterwards he had epileptic convulsions occurring in one of his attacks of dyspepsia. He had four more epileptic convulsions in the next two years, always occurring immediately after an attack of acute dyspepsia. Two and a half years ago he fell down stairs in an epileptic fit, and on recovering consciousness had complete loss of motion and sensation in the legs, following the blow upon the lumbar region. There has been a gradual return of power, though not complete. Since then he has stopped drinking to a great extent and has no more dyspepsia and no return of epileptic fits.

At the other extreme, we see cases where the tendency is so great that a sudden noise or a slight indiscretion in diet will induce severe attacks. It is not pretended that in all cases of epilepsy such provoking causes of the attack can be detected, but merely to bring into prominence the fact that the more closely we seek, the more frequently we shall find them, and that the avoidance of the attack is so important, and the recognition of the cause so valuable as a guide to restorative and preventive treatment, that a most critical and prolonged study in this direction is required in every case.

Turning now to the character of such provoking causes, I should mention as among the most frequent in my observation, first, indiscretions in diet, or improper food. I have already stated that this cause seems frequently to develop the tendency to the disease by impairing nutrition and inducing instability of nerve tissue, but also when such instability exists it very often serves to provoke the attacks. It may excite them by causing increased local irritation of the mucous membrane which will act in a reflex manner, or it has often seemed to me that it acts in some cases by inducing a condition of toxæmia from the admission into the blood of elements imperfectly elaborated, or from the failure of the emunctories to remove some product of malassimilation.

We are becoming more familiar with the wide range of symptoms, largely nervous in type, associated with the condition inadequately named lithæmia. In a considerable number of my epileptic patients it has seemed to me that their attacks bore a close analogy to the attacks of vertigo, for instance such as we see induced in lithæmic patients by indiscretions in diet. I believe it is difficult to lay too much stress upon the part which disorders of assimilation and nutrition, and the derangements of the associated functions of the great abdominal organs, stomach, liver and kidneys, play in the production of instability of nervous centres and the varied demonstrations or phenomena of such disorders as epilepsy and hysteria.

In this connection, it is interesting to again revert to the frequency with which scarlatina seems to have a causal connection with epilepsy. This may be explained in some cases by the tendency to wide spread tissue-change in this disease so that impaired nutrition of the gray nervous matter might be expected sometimes to occur. But it seems to me probable that in many other cases it may act by leaving such a degree of renal insufficiency as will under comparatively slight causes lead to toxæmia, due to the retention of malassimilated materials. It does not seem necessary that such a condition should reveal itself by the presence of albumen in the urine, although the statement of Huppert (*Archiv für Psychiatrie*, 1877, p. 189) that immediately after epileptic attacks albuminuria is almost invariably present and hyaline tubecasts can frequently be found, (while certainly exaggerated and not fully confirmed by subsequent investigators), calls attention to this interesting question. The cases of epileptic convulsions to which I especially refer, are those where previous to the seizure some derangements of digestion or secretion make themselves evident for a short time. Failure, impairment, or alteration of appetite, dullness, languor, with heavy aching sensations through the limbs; changes in the appearance with heaviness of expression, coating of the tongue and foul breath; constipation with alterations in the appearance of the urine, this and other similar premonitory symptoms will be found of frequent occurrence if carefully inquired after, and point in the direction of what I have been saying.

Among other provoking causes are excessive excitement; sexual excesses, inducing exhaustion; alcoholic excesses; great intellectual exertions, especially if associated with the excitement of competition; and excessive muscular exertion. A single severe muscular effort may suffice to induce the attack (see case 10). The importance of this is especially marked in cases where there is cardiac weakness. In the following case, where I could detect no disturbance of the heart's action, fatigue induced by muscular effort certainly increased the attacks of petit mal.

CASE VII.—Marion S., age 22, no hereditary tendency, began at the age of 19 after a course of excessive study at college combined with injudicious habits of life, to have characteristic minor attacks marked by palor and brief but complete loss of consciousness. She was a girl of strong will without the slightest hysterical tendency. No cardiac lesion or albuminuria. Attacks recurred at irregular intervals and close study revealed that they were apt to occur in connection with menstruation or to follow decided muscular exertion, for instance when driving her horse became startled, and while she was not at all alarmed it was necessary to use powerful exertion to control the animal. Following this there was a series of minor attacks at short intervals. Rest in bed for several weeks with gradual return to exercise but with complete rest at the menstrual period, carefully regulated diet and dialyzed iron in ascending doses broke up the spells which have now been absent for more than two years.

In those cases in which the morbid state of the

nervous system has been brought about by sunstroke, the attacks will often be induced by exposure to excessive heat, or to intense light. Of course, all these causes become operative on account of the morbid sensibility and instability of the nervous tissues.

It is often said that many epileptics are in full health. This certainly does not coincide with my own observations. Rarely has it failed to be the case that a critical study has not revealed either some organic trouble or some marked functional disorder. We do not speak of a lithæmic patient who has vertigo or other lithæmic symptoms on trifling indiscretions as being in perfect health.

The principles of rational treatment would seem to follow from a consideration of the points to which I have briefly referred. In no disease is routine treatment less permissible, and in no disease is attention to hygiene and general influences more essential. In each case the treatment should be adapted to the special peculiarity, to the character of the primary cause, if such can be discovered, and to the character of the provoking cause if it can be detected. Among the general principles which could be dwelt upon, I shall briefly allude to the importance of relieving anæmia and neuræsthenia and the morbid susceptibility by diet, by change of occupation and residence, and by rest. I would dwell upon the special value of prolonged rest in certain cases, which in my own experience have been chiefly met with among growing children. As for instance in this case :

CASE VIII.—Epilepsy apparently cured by prolonged rest, careful diet, with small doses of bromides.

F. S., age 15, a boy of unusual intellectual powers, and very ambitious. He had convulsions while teething and at the beginning of scarlatina, at 3 years of age. Healthy until 8, when epileptic attacks made their appearance, and proved obstinate, yielding only when he was removed from school and sent to a farm, and kept under the influence of small doses of bromide. He was then allowed to return to school, but after again devoting himself to his studies minor attacks began, and they were soon followed by frequently returning nocturnal severe attacks. These recurred with increased frequency. They were not controlled by bromides. The urine contained neither albumen nor sugar; no cardiac lesion. Appetite was good, but previous to this last outbreak of the attacks and during it, he had too frequent movements of the bowels—not actual looseness, but two or more occurring in the day, and usually with some little mucus. The minor spells occurred during the day, the severe convulsions in the night or early morning, and finally by February 1, 1883, more than one occurred in a single night. Congenital phymosis existed, but as no irritation appeared it was allowed to remain. He was then put to bed and kept there constantly, with very carefully regulated diet, 10 grains of bromide of potassium and 2 grains of quinine twice daily, substituted later by cod liver oil. He remained in bed strictly for two months and a half, during which time his attacks, both major and minor, ceased entirely. He grew and gained weight while in bed. The disposition to looseness was controlled

entirely by diet. The bromide was suspended, cod liver oil continued. He was then cautiously allowed to rise for a short time each day, and gradually increased until he returned to his ordinary mode of life. There has been no relapse in fifteen months, and a cure is apparently complete.

It is especially in these cases where there is anæmia, defective nutrition, and neuræsthenia, that cod liver oil, iron, strychnia, arsenic, and quinine have proved so valuable.

Gastro-intestinal irritation should be relieved. Possibly this is more especially applicable to cases where the aura is in the pneumogastric area, although it is applicable where the aura is absent or is in the course of other nerves. It is certainly applicable in cases of gastro-intestinal catarrh. In some of these cases, extreme benefit will be obtained from an absolute milk diet. The following case is of great interest in illustration of this statement :

CASE IX.—Charles Wilkinson, family not strong; disposed to be anæmic and somewhat nervous. One sister had marked anæmia; a brother had incipient phthisis of right apex, cured by long treatment and change of climate, and his father suffered a great deal from gastric trouble. Charles is now 19 years old, and was apprenticed to a plumber at 16½, when he seemed very well. He worked hard, and when two years older he had a severe pain in the back, which was either rheumatic or spinal, probable the former, and was treated under the name of meningitis, and was confined to bed for five or six weeks, and did not recover entirely until he came under my care. This trouble in the back seemed to be lumbago; it was in the lumbar region, and affected him so that when he was in a sitting position he could scarcely rise, but after he had walked a little he grew easier. There was no vomiting. He ate rapidly and heartily. The pain in back began quite severely, though he kept about for two or three weeks. Then, when at work on a roof, in March, 1881, he was seized with such intense pain in the back that he had to be helped off the roof, and was brought home and put to bed. While in bed, two or three weeks later, he had his first epileptic fit (the first one followed administration of a dose of oil, and was more like a syncopal attack). Then he had for at least three months (every day, or at most every third day) similar spells of sudden unconsciousness, eyes fixed and staring, no convulsive movements—lasting a few moments or two or three hours as though dead—occurring by day or by night. Face pale, but not as in a faint. Breathing very gentle during attack, and as he came out of it, very deep and heavy. He would have no consciousness of it afterwards. When they came on he would say, "I am sick; I am sick," and then go off into unconsciousness. Towards end of the two months these spells grew more frequent, even several in a day, always the same. When suddenly while lying in bed, to which he was confined then from pain in the back (lumbago?), he was seized with a fully developed violent epileptic attack (no apparent cause, and no excitement).

He was then using bromide of potass. and bell., and had eaten that day two bananas. [It is to be noted

that there was no vomiting, but his tongue was coated. He often complained of being sick all over. Appetite poor, flatulent, constipation, for which purgatives were given (senna and prunes), and the attacks were always preceded for an hour or so by great distress in the stomach. The stools contained mucus, jelly-like, greenish.]

After this he continued to have violent epileptic attacks every few days, until by September 1, 1881, they were two or three times a week. In the intervals he would have the peculiar *petit mal* as above described. The spells were all complete. He would feel they were coming—not always, for he had them during night in sleep—pain in stomach, like a cramp; often sudden flatulence, the stomach swelling up in two or three minutes. He would fall if not caught. Convulsions very long and severe, followed by stupor; frothed at the mouth; never bit his tongue; had no consciousness or recollection of the attack. Treatment by large doses of bromides and laxatives continued. He gradually got better of pain in back, and in course of ten or twelve weeks from the beginning he could leave bed, though he did not walk out before August, and then always with a companion.

I saw him in September, when he was looking poorly—pale, thin, and anæmic. Marked gastric irritability; connection of attacks with gastric disorder suggested itself prominently. He was then having his attacks very frequently, nearly every night just after falling asleep, and not rarely, also, one or two during day.

He was ordered strict milk diet, $\frac{3}{4}$ ss every two hours, gradually increasing to two quarts. This was continued for three months; not a crumb of bread during this time. Nitrate of silver and opium, inunction, twice daily; also nitrite of amyl, which stopped the attacks, if there was a chance of using it. The attacks continued for three months, growing less and less severe and frequent, and then stopped, and he had none for nearly a year. He regained his health; was able to return to work. Subsequently he has had six or eight attacks at long intervals, when careless in diet or when he overworks.

No bromide at all was used. On one occasion he had two or three attacks at shorter intervals, and I confined him again to milk and gave him a course of silver, after which he had no spell for a long time.

No treatment now for a year; no spell during that time, except once after mental worry he had a slight attack.

CASE X.—B. F., age 11. His father was of a highly nervous temperament, and had one uncle an epileptic, who died aged 38, of rapid phthisis. The maternal grandmother had heart disease, and for 20 years before her death had convulsions frequently, about once in two weeks. One grand-aunt had paralysis. His mother had two sisters, both of whom died with kidney disease with frequently recurring convulsions. One cousin had convulsions. While his mother was pregnant, she was much worried about her mother, who was then having convulsions, and died three months before the patient was born. He had distinct carpo-pedal contractions with fever when teething. His stomach was always very sensitive, and

the least excess excited fever. At such times, curious spells of rapid, sighing breathing would occur, and would recur until an emetic was administered, after which they would promptly cease. In August, 1880, when seven years old, he fell from the second story, striking his head upon two nails projecting from the wall and then striking the floor, but not losing consciousness. Soon after this, he began to complain of minor attacks, consisting of transient rapid vibration of the tongue, which he called "quivering," without loss of consciousness. I saw him first in October, 1881, and detected organic mitral insufficiency. He had been cutting teeth recently, and the minor attacks had been more frequent. His first severe convulsion occurred in November, 1881, connected with dental irritation. Bromides were given in small doses, extreme care was used in diet, and no convulsions occurred until the following summer, when dental irritations about the incisor teeth presented themselves, and quivering attacks began at once, occurring frequently; and he soon had two severe convulsions. After dentition was established, his attacks became much better, but in September, 1882, in spite of bromides in large doses, minor and major attacks recurred. I then found tightly adherent prepuce, with much irritation. This was separated, and the attacks again ceased, although bromide was now abandoned, as it had failed to control attacks. There was now a period of immunity for a number of months, during which time excessively careful diet was used, and, whenever there was evidence of irritation of the system, chloral enemas.

Since then there have been several outbreaks, the minor attacks of quivering growing frequent, and full convulsions occurring at short intervals. On one occasion, such a state was directly induced by violent straining muscular effort trying to lift a heavy weight, which brought on severe cardiac disturbance. Strict rest in bed, digitalis and very careful diet, with a few chloral enemas, broke this up. On several other occasions, the development of these periods of activity has been preceded for a few days by evident disorder of assimilation, the complexion growing thick, dark rings under the eyes, breath heavy, stools less natural. Under such circumstances, neither bromide or chloral enemas have stopped the convulsions. An emetic of ipecac in warm water, with very rigid diet and almost complete rest, have broken up the spells, and have secured immunity for a number of months. In this way, there has been a great improvement during the past 18 months without any bromide, and with the use of only occasional chloral enemas. Moderate study with a tutor has been permitted. The boy is developing finely, physically and mentally. The organic heart disease remains the same. The attempt has been made to arrest the quivering by a clamp which he carries to apply to the tongue, but without definite results. Nitrite of amyl always succeeds when opportunity is given. Bromides in any form, even in small doses, have lately seemed to disturb digestion, and do more harm than good.

It seems that it is in these cases, where the connection between the gastro-intestinal mucous membrane and the nervous system is so prominently marked,

that nitrate of silver is especially useful, either with or without the conjoined use of the bromides. I would also call attention to the importance of the occasional use of emetics in cases where the occurrence of attacks is accompanied by evidences of increased gastric disturbance. It has happened in my experience that, when spells of unusual severity were occurring with unusual frequency, despite the use of various anticonvulsives in full doses, the use of an emetic has been followed by an abrupt cessation of the attacks, and by immunity for a considerable period. (See case X.)

Over-exertion should be avoided in all cases, and especially in cardiac cases as will be seen from several cases which I have reported. It is in these cardiac cases that digitalis seems to be of value. Excitement, over-work and excessive study is to be avoided. Study in private should be preferred.

Counter-irritation and the removal of local irritation. In the first place I should allude to the value of the actual cautery, especially when intra-cranial irritation is suspected, as, after sunstroke and after injury without demonstrable lesion, and even in organic cases, although we cannot think that the actual cautery could influence the gross cerebral lesions, yet its effect on the nervous system is sometimes such as to secure immunity for a considerable period.

Trephining. It is my conviction that this operation is not performed often enough for epilepsy. We may ask ourselves if it would not be proper to do the operation when the position of the discharging centre can be located by the aura, the character of the convulsions or from a history of an injury, even though no positive lesion of the cranium exists? When there is a demonstrable lesion, it should be performed.

Adhesions of the prepuce are to be broken up by dilatation, and the redundant prepuce is to be removed by circumcision, although from my own experience, I should say that the importance of this has been greatly over-estimated.

Lastly, the arrest of the attacks. Ligature and nitrite of amyl are useful in preventing individual attacks and in checking the formation of a habit. I have purposely confined myself to these general measures, omitting any reference to the drugs usually employed, notably the bromides. I have done this not because I fail to appreciate the enormous value of the bromides in epilepsy, or the fact that the discovery of the anti-convulsive powers of these agents has actually modified the whole question of prognosis in epilepsy, and rendered the disease more manageable than it formerly was, but because I think that there is reason to believe that the profession has drifted too much into depending upon the bromides, prescribing them in every case without studying the individual peculiarities sufficiently, and as a moderate dose fails, to increase it and continue it for a long time, until this course finally produces results injurious in themselves, and calculated to hinder the restoration of nervous power and the removal of the fundamental condition of nervous susceptibility and instability upon which the disease essentially depends.

Bromides do not cure epilepsy, except in rare in-

stances. More frequently they control the disease, sometimes indefinitely, but more commonly losing their effect gradually, and this is the worst feature about them. In other cases, they fail to control the convulsions, and there are a few cases where the bromides have seemed to be actually injurious by depressing the digestive power, if they did not actually cause gastro-intestinal irritation. I shall not discuss the selection of the special form of bromides or any particular method of administration. The bromide of potassium has seemed to be the most valuable. Occasionally, it has been desirable to substitute this or combine it with some of the other bromides. As to the mode of administration; they should be given at first in minimum doses, and no more than is sufficient to control the convulsions should be administered. In many cases, I have found it necessary, after using the bromides, to either abandon or modify the treatment, and I have concluded that far more value is to be attached to hygiene, diet, and the more general remedies, than is to be attached to the bromides.

In like manner, I shall not attempt to allude to the other drugs, such as belladonna and other antispasmodics, which have been recommended, but will close with a brief allusion to the effect of enemata of hydrate of chloral, as having given good results in some cases where the bromides have failed. Often far better results are secured from enemata of chloral, than can be obtained from the administration of the remedy by the mouth. This method is of particular service where the administration of the bromides and chloral by the mouth seem to be disadvantageous on account of their tendency to disorder the stomach and digestion.

DISCUSSION.

Dr. Austin Flint, Sr., of New York, opened the discussion on the subject of Dr. Pepper's paper as follows:

An argument for the toxical pathology of epilepsy is not, as it seems to me, out of place in a discussion of that affection from the standpoint of the medical practitioner, inasmuch as our inquiries with regard to the prevention and treatment of diseases must, in a great measure, receive their direction from pathological views.

By the phrase "toxical pathology," I mean to express the doctrine that the manifestations of epilepsy depend on a toxical agent of some kind, produced somewhere within the body.

The first point in the argument is the absence of any generally received or satisfactory pathological doctrine. I assume, as a postulate, that epilepsy has no established anatomical characteristics. It may be associated with different lesions, and in a certain proportion of cases no lesions are discoverable. A rational inference from these facts is that different associated lesions, when present, have only an incidental pathological connection with the disease, if the connection be not purely accidental, and that the disease is essentially one of the neuroses. It may also be assumed that the manifestations of the disease generally occur without being preceded or accompanied by any apparent morbid conditions which may

be supposed to be causative. As a rule, epileptic manifestations have no distinct premonitions. They occur wholly irrespective of any causative agency from without. The varied sensations which have been described under the name *aura epileptica* are in most instances wanting, and the diversity in their character divests them of any special pathological significance. Pathological explanations such as are expressed by the terms "discharging lesions," (Hughlings Jackson) and "excitability," (Brown-Séquard) are not only purely hypothetical, but they convey nothing clearly explanatory. It may be said of the etiology, as well as of the pathology, that there are no obstacles to be removed in order to make way for a new doctrine.

The second point in the argument is the analogy between the phenomena of epilepsy and those known to be produced by toxic agents. The closest analogy exists between epileptic paroxysms and uræmic coma with convulsions. No one at the present day, doubts that the coma and convulsions referable to renal disease, are caused by retained urinary principles. Yet, within my recollection, uræmia not being recognized as a morbid condition, the coma and convulsions dependent thereon, were as indeterminate in respect of their pathology and causation as are the phenomena of an epileptic paroxysm at the present day. An attack of uræmic coma and convulsions may simulate a paroxysm of epilepsy so closely that the latter could not be discriminated from the former without the information to be obtained from an analysis of the urine. I have known several attacks of uræmic coma and convulsions to have occurred, and been considered to be paroxysms of epilepsy. On the other hand, in some cases of epilepsy in which the paroxysms recur after short intervals during many hours and even days, there is so close a simulation of uræmia that an examination of the urine is essential for the discrimination. Reasoning on the principle of like effects being referable to like causes, I submit as a reasonable conclusion that the pathology of epilepsy, in the same sense as the pathology of uræmia, is toxic.

As a fourth point in the argument, certain facts pertaining to the clinical history are more rationally accounted for on the supposition of a toxic causative agent, than by any other explanation. The facts referred to are, 1st. The absence of any definite ailments prior to the occurrence of an epileptic paroxysm, there having been no ailments, or those which may have existed being of an indefinite character expressed by the term *malaise*. This fact is alike applicable to certain cases of uræmic coma and convulsions. 2nd. The short duration of the epileptic paroxysm. 3rd. The immediate recovery in many instances of the general condition of health which existed prior to the paroxysm, and not infrequently a feeling of improved health. These facts are more consistent with the supposition that the epileptic paroxysm is due to the transient accumulation of a toxic agent, than with any other pathological consideration which may be supposed to exist. It is to be remarked, however, that the toxic pathology by no means excludes the probability that certain local

morbid conditions are more or less important, and may be essential, or auxiliary, constituting a susceptibility to the action of the toxic agent.

As a fifth point in the argument, facts pertaining to therapeutics uphold the toxic pathology. Nothnagel in his treatise on epilepsy, opens up the consideration of the treatment in these words: "Small indeed is the actual encouragement derived from looking through those chapters of medical literature, from the oldest to the most recent times, which refer to the treatment of epilepsy. The methods and the remedies change; but the final result always remains the same beggarly one!" I presume no one will deny that this statement expresses truthfully the actual state of our present knowledge of the therapeutics of epilepsy. From this statement it may be inferred that up to the present time pathological views have failed in giving a successful direction to therapeutical observations. Of the remedies which within late years have been found to have a certain amount of influence over the disease, namely, the preparations of zinc, belladonna and the bromine salts, the most rational explanation is that they enable the nervous system to tolerate, to a greater or less extent, the toxic agent on which depend the manifestations of the disease.

It is needless to say that in this brief paper I have merely touched upon the general points in the argument for the toxic pathology of epilepsy, and I have omitted points which might be adduced. The limitation as to time (10 minutes) has prevented a fuller consideration of the subject. Accepting the toxic pathology of the disease, the pathological inquiries to which it gives rise are, what is the *modus operandi* of the toxic agent, what is its nature, whence is its source, and what is the mode of its production?

The questions which relate to the practical applications of the doctrine are, how can the production of the toxic agent be prevented, how can its morbid effects be neutralized, and how can it be eliminated from the body? In answer to these questions at the present time, nothing could be offered but conjectures.

Dr. P. O. Hooper, of Arkansas, remarked that little or nothing can be offered or suggested or added to the exhaustive paper of Dr. Pepper, for no subject in medicine has received more elucidation than epilepsy. It is interesting to note the steps of progress in the numerous investigations which have led to results nearly as clear as absolute demonstrations; so plain as to be accepted with singular unanimity by all who have carefully given the subject a thought. The one fact received, that anæmia of the brain and spinal cord is the direct cause of epilepsy, explains its phenomena in all their varied phases. Leaving out the classifications of *grand mal*, *haut mal*, *petit mal*, and the like as unnecessary, if the enquirers will regard both the disease and its direct cause as unities, it seems that a great stride will have been made in the direction of the simple truth as to its nature, causes, pathology and treatment.

C. J. B. Williams gave the key-note in vascular

pathology when most of us were pupils. He has been followed by Addison, Waller, and Conheim. In another direction, Claude Bernard, Brown-Séquard and others were pursuing their studies of the nervous system. Others have been giving special attention to phenomena affected by the results of investigations in these same directions. Notice, epilepsy, as has been said, is the immediate effect of a sudden anæmia of brain and spinal cord. Analogy indicates as much, as shown in animals when bled to death. Post-mortem examinations and vivisections afford almost conclusive confirmation. Now, what superinduces the sudden anæmia? Constriction of vessels supplying the nervous centres. Then, an irritation anywhere, or from any cause, in certain predisposed constitutions may be sufficient to effect it, and the usual central and peripheral causes; whether the irritation exists in one tissue or another; whether it is found in brain itself, in the alimentary canal, uterus, or muscular tissue, or wherever it may be, the result is exactly the same. The irritation is conveyed by a sentient medium to the nerve centres, and reflected. In its course the motor filaments are influenced by the distribution of the sympathetic, and the vascular supply of the part to which the reflection tends is modified. If the point of tendency happens to be in the line of the nerve centres, and the modification should be a sudden constriction, epilepsy in some of its protean phases would be looked for, because the circulation would be suddenly shut off, so to speak, and the consequent anæmia give rise to epilepsy.

A late very excellent work by Dr. E. C. Mann, says in substance, that it seems very probable that owing to functional disturbance of the vaso-motor nerves which are distributed to the cerebral blood-vessels, we have during an epileptic paroxysm, primarily the vascular tonus just referred to, causing sudden anæmia of the brain, followed immediately by congestion and hyperanæmia.

The whole motor tract of the cerebrum, and also of the spinal cord, is undoubtedly connected with the production of epilepsy; and probably, also, the motor nuclei in the medulla oblongata and on the floor of the fourth ventricle, and the corpus striatum, as one of the centres of motion, is also concerned. The conclusion of this writer is irresistible, the *rationale* is clear, and the theory most plausible. Accepting this line of reasoning as true, a flood of light is thrown upon both the endless variety of manifestations in which the malady shows itself, and the efficacy or want of it of the almost endless list of remedies and remedial agencies that have challenged the consideration of practitioners.

The manifestations will depend briefly as follows: Upon the constitution of the patient and the nature and locality of the irritation. In respect to the former, an unstable, nervous organization, whether hereditary or acquired, is of the first importance as tending to a predisposition; as to the latter, they are endless in variety. In the treatment, any means or measures that will create and maintain a steady tone of the vessels which supply the nervous centres would be esteemed as most useful, whilst an agent sufficiently sedative and tranquilizing to guard and protect those

tissues against the assaults of irritating influences, would rank as desirable adjuvants. Nitrate silver has long maintained a reputation based no doubt upon its tonic powers, but lately ergot has attained a recognized supremacy. In fixing attention to the bromides as almost a specific, Sir Charles Locock takes the attitude of a great benefactor to the race.

It would be futile to look for the remedies indicated without such an examination as would serve to locate the prime cause or irritation. Wherever found, its removal is a matter of first consideration. The agencies and methods must be determined by the facts and circumstances of each particular case.

Dr. Eugene Grissom, of N. C., remarked as follows:

Epilepsy as an *organic* disease is usually inherited, either as such, or as a sequel of some other neurosis. It is preceded, for the most part, by one or more eclamptic seizures in childhood, and commonly makes its onset at the period of puberty.

It may be the result of conception during drunkenness, or after any other prolonged depression of the system, leading to its enervation. It may serve as the representative of chorea, or of partial paralysis in the father, or of hysteria, or any wasting uterine or ovarian affection in the mother. It may accompany such disorganization of the brain as results from syphilitic cranial changes. It may appear in the child of phthisical, or scrofulous, or rickety parents. Finally, it may be the last expression of an ancestral history of degeneration, traceable, perhaps, for many generations (like the royal house of Spain), on its way downward, to extinction in cretinism.

The influence of hereditary bias in developing the unstable nervous condition which eventuates in epilepsy, from a parentage either already affected by some recognized neurosis, or else so far weakened and degraded from a normal vital standard by a succession of either moral or physical causes of depression, as to fail of nervous nutrition; this influence, I say, is acknowledged by all who have studied the statistics of this interesting subject. It is clearly exhibited by Echeverria in a table of 532 cases, and conceded by all writers of note.

It is hardly to be expected that any course of therapeutics can create a man anew, and restore in a single lifetime, the losses resulting from misused minds and bodies. It is impossible to repair in a day the long-continued breaches of systemic integrity made by persistence in evil habits, mental or physical. When, therefore, organic or idiopathic epilepsy is recognized, as clearly the result of gradual and profound degeneration, the prognosis cannot be hopeful.

The extremity of the difficulty lies in the very fact that the channels of restoration are themselves choked. If *pain* is the expression of *mal-nutrition*, the epileptic movement is believed to be, in the highest degree, the result of *in-nutrition* of the nervous centres. The very circulation through the vaso-motor apparatus, is disordered, irregular and fitful, and the stimuli to which the system would ordinarily respond with advantage, whether of food, or exercise, or sensory irritations of whatever character, are capable of becoming transformed to excitants, through the trophic

changes, by which the normal action is driven into tortuous and abnormal influence upon nerve centres, in the victim of epilepsy.

The deep-seated obstacle to a scientific therapeutics would seem to be the inability to control the channels of communication, in the case of the confirmed and inherited epileptic. The actions and reactions of ordinary organic life are modified by the introduction of a mysterious element, which capriciously breaks for a moment the usual interdependence of nerve or muscle, or nervous filaments and their appropriate centre. The expression of the face is gone, the voice changes, every muscle has taken upon itself strained and forced, perhaps unnatural uses; more than all, and most significant of all, the mental manifestations are those of another and apparently foreign creature—everything denotes that the fountains of the depths of being are broken up. We are not to suppose that all this irregularity of muscular and nervous movement on the surface, and this utter change of psychical expression, can be unattended with deep-seated change in glandular action, in the nutritive movements of the system, and, indeed, in the chemico-vital processes in general.

It will be necessary to discover the secrets of the transmission of nervous force, before we can pronounce authoritatively upon the genesis of epilepsy, whether considered as the ultimate result of *lives* which disorder nutrition and disarrange nervous distribution, or as an immediate consequence of any agency of depression.

But that branch of the subject which is more fruitful of hope for the medical man, is the consideration of *functional* epilepsy—of that symptom, perhaps, rather than disease, which may be present in almost every disease, as some writer has remarked—which may accompany what is apparently a slight intestinal irritation, as from the parasites which abound in childhood, or from dentition, or the changes incident to menstruation, or the change of life; or, again, from such traumatic causes as a blow on the head or spine, a sunstroke, great cold, and certain moral causes like excessive fright, which sometimes strike down the system with such force that life itself hardly rallies after the blow.

The functional form of epilepsy is by far the most frequent, and its alleviation or cure demands, and ought to receive, much more pains-taking care and attention than it usually receives from the general practitioner. It is protean in its development, and must be met by protean efforts. Its two sources may be broadly defined as:

First. That which proceeds from any great draught upon the vital powers; as, in a physical sense, from a great loss of blood, leaving the nerve centres anæmic, or in a moral sense, from an overpowering fright, in some way producing the same anæmia by the shock, which leaves the nerve centre for the time being unable to appropriate the food required for momentary nutrition.

Second. That epilepsy which is set up by the suffering of the peripheral nervous trunks, from some perhaps minute but ever-irritating cause of disturb-

ance of the terminating nervous filaments, either of the cutaneous or of the splanchnoid distribution.

If one is tempted to ask whether, in the latter case, the *post hoc* has been taken for the *propter hoc*, let us ask ourselves how we can account for the terrific consequences of tetanus as a result of an insignificant wound, or the propagation of fatal erysipelas from a mere scratch, which has really injured nothing of importance to the system, provided the nervous and circulatory distribution were unharmed; or, again, the spectacle of hydrophobia from a nervous injury scarcely visible, and perhaps long forgotten?

But this subject has been set at rest by the results of modern treatment—by the brilliant practice of Dr. Sayre, in relief of epilepsy from irritation of the genito-urinary apparatus—by the successful application of the trephine to relieve epilepsy from the entanglement of nervous filaments in a cicatrix—by the effects of nerve stretching in diseases of a choreic or epileptic character, confined to the track of the nerves of voluntary motion—by the cases of Battey's operation in which relief has been obtained from epileptic disorder, and such other evidence as medical science is daily supplying.

It is characteristic of *functional* epilepsy that it expends its morbid power chiefly upon the nerves of voluntary motion, and those most frequently used;—as, for example, upon the great toe in the foot, or the index-finger and muscles of the forearm, or again of the tongue, lips and eyelids. How often does the interruption of the delicate movements of the tongue in precise articulation betray the first weakness in the power of coördination!

Therapeutic measures, therefore, which are to be adopted in addition to constitutional treatment, should be directed to the tonic regimen of the voluntary muscular system, which is in danger of losing the inhibitory control over its vaso-motor circulation, by reason of nerve-weakness.

The connection of epilepsy with anæmia has been shown by Van der Kolk and others. It is emphatically an affection associated with weakness; with atrophy, or with loss of tonic ability to maintain control over the circulation, and *with that*, and in a much more significant sense, want of control of those manifestations of the brain power which accompany the *conscious* exercise of will, memory or judgment. This topic, if pursued, would open the intricate, and as yet unsolved problems of moral responsibility within the circle of the epileptic eclipse.

Dr. Hughlings Jackson (West Riding Asylum Reports) affirms that the epileptic paroxysm is a sudden, excessive and rapid discharge of gray matter of some part of the brain. The gray matter, which is the seat of what he determines a discharging lesion, is in a constant abnormal state of nutrition, and hence it is constantly abnormal in its function. He represents the primary attack of epilepsy as the discharge of a part which has been for some time in a state of mal-nutrition.

Certainly it is perhaps *not* a rash supposition that the brain, acting as a whole, with its allied ganglia controls the operations of systemic and voluntary motion by the harmonious action of the forces whose

origin proceeds from the nerve centres, inspired under proper nutrition, when of normal construction at birth and without subsequent injury, with the *vis vite* that will probably forever elude investigation, however thorough and delicate. If this harmony is conceived to be maintained by the original propelling energy of each centre, and also by the inhibitory control which each possesses upon the others, to a certain extent, we can perceive that a failure of nutrition in any centre, may leave its reciprocal or corresponding centre without the checking influence essential to the due marshalling of the whole movement in voluntary action, under the command of the will, if we may venture upon a metaphysical term in considering a physical problem.

The epileptic affection is essentially a stoppage or a transformation of the movements, not of muscular centres only, which are the mere epiphenomena which attract our vision, but it is deeper and more important; the irregular, involuntary, and exhaustive discharge is most effective in its consequences when the upper sensory and cortical centres are shaken and disordered, and intellectual perception and moral responsibility are tottering, or for the time being lying prostrate under the physical storm which has spent itself upward, rather than merely shaken the victim with choreic muscular spasm.

Whether nervous movement proceeds from one molecule to another by chemical adaptation and momentary molecular change induced by affinities paralleled by isomerism, or through some as yet unknown development of force akin to action by electrolysis, or any corresponding method of the transmission of force, it would seem that in epilepsy there is an interruption to the transmission of normal movement, a separation of the links, a stoppage in the even flow of nutrition for the cells, which harmonious organic life demands.

In regard to the therapeutics of functional epilepsy, what we have said will, in a measure, indicate the treatment.

The most careful attention to diet is required to build up the system, and supply the nerve centres with a sufficiency of pure blood. Regular and systematic, but above all things *unfatiguing* exercise follows as a matter of course. Fatigue simply invites exhaustion, anæmia of the medulla, and the paroxysm. How often we witness the epileptic convulsion as a sequel of exhaustive effort. Such climatic tendencies and daily occupations and educative influences as tend to build up the whole man healthfully and happily, and thus to erect a brakewater against all that would harass, oppress, or wear the bodily or mental frame, are imperatively indicated. Much must be left to rest, to patience, to time, to consolidate new habits, and preserve new channels of normal nervous nutrition.

The topical effect of drugs and medication I need not dwell upon. In epilepsy from syphilis the iodide and mercurial preparations have been of value. The bromides, digitalis, atropine—all these are favored by those who seek to reduce the susceptibility of the medulla and allay erethism, if present, after the proximate cause has been removed. Zinc preparations

have been useful in irritations of the pneumo-gastric, *iron* in cases after chlorosis, *quinine* in general anæmic states, and *electricity* in primary affections of the sympathetic system.

Dr. T. B. Lester, of Kansas City, Mo., said, the clinical advantages afforded the general practitioner, are not such as enable him to throw much light upon a subject so obscure as epilepsy. Yet the comparatively few facts which he finds in his limited field of observation are important in making up the great aggregate of facts which we may reasonably hope will one day dispel the darkness which enshrouds the true nature and proper treatment of this disease.

The paper of Dr. Pepper to which we have just listened with so much pleasure and profit makes a strong plea for a rational treatment based upon the constitutional peculiarity and special causation of each individual case.

This course of treatment cannot fail to commend itself to every one, save those who pertinaciously cling to some cherished plan of routine treatment.

There can be but little doubt that a large majority of the functional derangements of the nerve centres, which give rise to the pathological phenomena of epilepsy of every grade, have their origin outside these centres themselves. The great difficulty which lies in our way in treatment is two-fold—our inability in many cases to remove the primary cause—and to restore the reflex and convulsive centres to their normal degree of excitability. It is comparatively easy to comprehend how a purely local peripheral cause long continued by its irritation of the reflex centres may ultimately result in such histological changes, so that, should we succeed in removing the primary factor, the epileptic seizures would still continue to recur. Such is the familiar history of epilepsy, and it teaches us the important lesson to be vigilant in our search for every probable source of irritation, and prompt in removing it by every means in our power; for it is positively beyond our ability to estimate the measure of damage there is in delay.

It is probable that those cases dependent on some constitutional disease—with rare exceptions—are developed through the *intermediate* influence of the malnutrition which they produce, and not from any *direct* toxic influence which may be exerted upon the nerve centres, through the agency of retained excrementitious elements or other products of mal-assimilation. This, I think, may be predicated of those cases having their supposed origin in syphilis, lead-poisoning, frequently recurring hæmorrhages, renal insufficiency, or other defective elimination, chronic malarial infection, mental or corporeal exhaustion, etc.

Any constitutional disease which produces general anæmia is competent to develop an epileptic seizure, upon the supervention of slight peripheral irritation owing to the increased excitability of the reflex, and convulsive centres, which anæmia is well known to produce. If this be true, how futile must be our treatment, if alone directed to the sedation of this increased excitability. This end can be oftentimes accomplished by the influence of the potassium bromide, but the relief must at best be temporary and

partial unless conjoined with the use of such restoratives as iron, arsenic, cod liver oil, nutritious diet, good sanitary surroundings, and freedom from over-taxation of body and mind.

Diminished arterial blood pressure, with its concomitant increased venous blood pressure, is competent to establish the same, or similar condition of malnutrition, as the other constitutional conditions before mentioned. I have a case under treatment at this time, in which the first seizure occurred at the age of 64 years, without any assignable local or constitutional cause, except the enfeebled action of the heart, incident to the degeneration of old age.

In this case potassium bromide has been tried, with the effect only of lessening the frequency and severity of the attacks while the patient was kept strongly under its influence, but under the conjoined influence of the bromide digitalis, iron, and cod liver oil, the case has been much improved.

If the paper of Dr. Pepper does nothing more than to direct the attention of the profession, in a forcible manner as it does, to the importance of a just discrimination, between the varied constitutional conditions which exist in epilepsy, to the end that we may treat it more rationally, it will have accomplished great good.

J. J. Caldwell, M.D., of Baltimore asked what is Epilepsy?

Epilepsy a disease—or a deficiency—or a disturbance of the brain and nervous system, whereby there is a sudden and deadlike arterial anæmia of the brain and nerve centres.

These phenomena may indicate functional or organic lesions, hence the disease may be curable or incurable. As a proof of the above proposition I will cite the following theories, facts and authorities:

A NEW METHOD OF TREATING ASIATIC CHOLERA PROPOSED.

BY S. S. TODD, M.D., PROFESSOR OF DISEASES OF WOMEN IN THE KANSAS CITY MEDICAL COLLEGE.

I do not wish in this brief paper to go into the subject of natural history of this disease. Thanks to modern investigation we seem to stand on pretty solid ground now with respect to its cause and mode of propagation, and the best means of warding off the disease, lessening the ratio of its mortality, and possibly its *fatality*—or the ratio of deaths to the number attacked.

More light is needed on the subject of the patholo-

gy of the disease, however, and especially is it needed that the experience gained in former visitations and the present advanced views concerning the nature of the disease shall give better results in treatment than have been had hitherto.

The plan of treatment here proposed, it may be said, has the perilous disadvantage of being a *proposition*—something untried. It is this fact probably that will most commend it.

The hypodermic syringe of half-drachm capacity is familiar to all, and I am inclined to think that many indulge in the futile hope that in the coming epidemic much good will be had from the use of the hypodermic syringe in the ordinary way. It does not seem to have occurred to any, however, that the capacity of this instrument may be so increased that, instead of a few drops of some fluid, quarts of water, medicated as desired, may be made to enter the circulation within a short space of time, and that the good results to be gained from the use of the instrument may depend almost solely upon its capacity to fill the depleted circulatory system rapidly with some desired fluid.

The possibility of doing this, even in cases of collapse, will hardly be questioned, and the *value* of the suggestion will we think be duly appreciated by those who have passed through an epidemic of this disease and witnessed the torrents of serum poured forth and lost to the circulation with every evacuation of the bowels, and seen the hours of pitiless retching of the stomach as it rejected everything put into it, either to relieve the maddening thirst or to restore to the organism its wasted fluids.

Some years ago I was led to believe that good results might be gained from the use of a syringe of such capacity as would allow of the introduction into the circulatory system, hypodermically, of large volumes of defibrinated blood, artificial serum, stimulants, etc., in cases ordinarily turned over to transfusion, as well as for the use of alcoholic and other stimulants in certain other adynamic states. No favorable opportunity of testing this method of transfusion has since occurred, but within the past two years I have, in some notable cases of great prostration tested the value of alcoholic stimulants thus administered. Two of these were cases of septicæmia—one of them after a labor and the other following on ovariectomy.

In each of these cases rapid and considerable reduction both of pulse and temperature invariably and repeatedly followed the injection into the cellular tissue of the thigh of from 3 to 6 drachms of whiskey (sometimes brandy) with an equal quantity of water, the effects lasting for about 12 hours. The force of the heart's action was always increased by the injection, the pulse losing in rapidity from 10 to 15 beats per minute and the temperature being lowered from one to two degrees,—to rise again 10 or twelve hours afterwards if the dose were not repeated. Both of the cases referred to resulted fatally, but in one of them I am sure that life was prolonged for more than a week.

In one case of threatened death from shock and loss of blood during an ovariectomy, the patient's life was saved by an injection of two ounces and a quarter of

the above named mixture. No ill-effects were seen to follow these large doses, and I am of the opinion that in certain cases the quantity of the alcoholic liquor might be increased with safety to two, or even more than two ounces, if sufficiently diluted. The cases tolerating so large a quantity would be those where there had been exhaustive hæmorrhage, or great loss of blood serum as in cholera.

The object to be gained by the proposed use of the syringe in advanced stages of cholera is this: that, without tasking the stomach, we may flood the circulatory system with an artificial serum that shall supply the place as near as may be, of that which is being wasted, and also to introduce in sufficient quantities alcoholic, or other stimulants, and whatever else may be indicated.

The course of treatment then to which I wish to direct attention, and with the value of which it is perhaps needless to say I am profoundly impressed, would, without going into details, be something like this: All cases in their incipency, and all *mild* cases throughout the attack should be treated with opiates and astringents, and *hot* water acidulated with sulphuric acid should be allowed, and urged upon the patient, to the utter exclusion of ice, ice-water, and all ice-cold drinks. Whiskey, wine, or brandy may be added if the patient be much prostrated, or be suffering from fear, but in moderate quantities only. The abdomen should be covered with a large mustard poultice, and the feet should be kept warm.

In a more advanced stage of the disease and in all severe cases, from the outset no time need be wasted with opiates or astringents, as they will do little good. Collapse is now imminent, and the hot drink should now be given more assiduously than before, and repeated again and again if the stomach reject it. The body should be kept as warm as possible with bottles of hot water or other appliance, and no rubbing allowed, if the patient can be otherwise kept quiet, as it limits the advantage to be gained from application of heat, an important consideration. Ice and ice-cold drinks, contra-indicated in all stages, are most hurtful in this, and however grateful to the patient, and however eagerly craved, should be rigorously denied, as tending to cause, or aggravate an already existing algid condition.

It is now that the hypodermic syringe is to prove useful, if at all. Large quantities of a fluid should be injected, at short intervals, composed of distilled water to which has been added a small quantity each of chloride of sodium and chloride of potassium, and such an amount of *alcohol* as may be deemed requisite, the solution to register 98° F. when ready for use. These injections should be repeated at intervals of one or two hours, the interval, the quantity of alcohol, as well as the whole amount of fluid used, to be regulated by the amount of serum waste, by the degree of prostration, and by the size, age, and sex of the patient. It may not be out of place to say here that the writer has passed through the midst of two cholera epidemics. A syringe of 4 oz. capacity may be had of Geo. Tieman & Co., 67 Chatham street, New York.

Kansas City, Mo., July 22, 1884.

A NEW FARADIC BATTERY AND ITS USE.

BY ROBERT NEWMAN, M.D., NEW YORK.

Read before the Section of Practice of Medicine of the American Medical Association at Washington, May 8, 1884.

The object of this paper is to urge the necessity of having a reliable faradic battery ready to work, at a moment's notice, in every practitioner's office; and to exhibit here a new improvement, which promises the completion of this desideratum.

The faradic current of electricity acts chiefly "mechanical." From reports of clinical cases, it seems that it has other qualities, which at present are not sufficiently defined, but unquestionably the principal action is "*mechanical*." It is a mistaken idea, which some entertain, that a faradic battery has some galvanic action, because one part of such a battery consists of one or two cells. The patient never gets an effect from these cells, as they act solely as a motor power to the induction coil; and never can give galvanism.

The faradic current acts through the nerve-filaments on the muscles; its passage through the nerve produces each time a mechanical concussion, it provokes the excitation of the motor and sensitive nerves, and thereby causes contraction of voluntary and involuntary muscles.

Therefore the most important use of the faradic current in medicine must necessarily represent a "passive motion," in all cases where active motion is impracticable or impossible. In practice this electricity, therefore, will be used in all kinds of paralysis in which the muscles have not lost their electric contractibility; in accidents of poisoning and asphyxia; in all cases of temporary suspended animation. In the latter class of cases life is lost by a failing of the heart's action. The indication therefore is to sustain the circulation by the regular pulsation of the heart, until the poison is eliminated from the system by antidotes, and the heart resumes its function naturally. Many lives have been saved by the prompt application of the faradic electricity.

It is therefore of the greatest importance to have a battery always ready for action in cases of emergencies. One important cause why electricity is not as popular among the profession as it should be, is the want of a good battery, which is ready for use at a moment's notice, and works without fail, which is so portable, that it will neither break, nor spill the fluid, when carried about. I greet with pleasure a new and very simple invention, which promises to supply this want.

It is a new portable faradic battery, connected with and inside of dumb-bells. It can be used separately, or while exercising with dumb-bells.

The battery, either in use or at rest, is so secured that the fluid can not be upset, no matter how it is thrown about. While the battery is in full operation, the end of the zinc stopper acts at the same time as one of the elements. If it is desirable to save the zinc, while the battery is at rest, the stopper of zinc can be exchanged with another stopper of rubber, which also closes the battery hermetically.

This battery can be transported in any possible position, taken in bed by the patient, carried about town, placed in the carriage of the doctor, rolled about on board a vessel, used in the gymnasium, or any room, and in any position. It works as primary or secondary, and both currents may be used in combination. The electro-magnetic power can be regulated from weak to strong, by degrees, at will. There is at present not one battery in existence, which fulfills these indications, notwithstanding advertisements may represent it as such.

This drawing represents the battery itself, (without the helix).

EXPLANATION OF FIGURE.

- (a) Round flask of hard rubber.
- (b) Lining of carbon, representing one element.
- (c) Cavity for fluid.
- (d) Stopper of zinc, representing the second element, upper part surrounded by soft rubber, closing hermetically.
- (e) The opening of flask for filling, and closed by stopper d.
- (f) A platinum peg, pressing a spring downwards, and connecting with helix.

You will see here the battery proper, consisting of a hard rubber thin hollow flask, which can be manufactured so small that it can be carried in a waistcoat pocket, or ordered of any size for a large battery. This flask is lined inside with carbon, acting as one element. The principal novelty is the stopper, a round piece of zinc, which is the second element. Its upper portion is surrounded or packed with soft rubber, which closes the flask hermetically, so that no fluid can be spilled. The flask is filled with an aqueous solution of bisulphate of mercury, or any other generating fluid. When this little battery is placed in its wooden encasement, it is perfectly safe from any injury. A platinum peg inserted through the lower part of the hard rubber flask presses a spring

downwards, which is connected with the helix of the battery, and sets it in motion. In principle, the instrument is like the Gaiffé battery, but it is stronger and keeps in active motion many hours.

The beauty of the invention is its simplicity, and its important part is a lump of zinc, which closes the battery hermetically and acts at the same time as the second element. This closure also prevents the evaporation of the battery's fluid. The ingenious inventor is Dr. Louis Drescher. I hope that the principle will be applied in such a combination that we will have soon a portable galvanic battery in its widest meaning of the term.

MEDICAL PROGRESS.

ANATOMY AND PHYSIOLOGY.

ON THE ACTION OF THE INTERCOSTAL MUSCLES IN RESPIRATION.—M. Laborde, who is in charge of the physiological work of the Paris faculty, has been making some experiments upon the body of a criminal called Campi, who was guillotined in Paris, April 30. Having everything prepared for his purposes, the body was received at the laboratory, one hour and twenty minutes after the execution. The description of the experiments as given in the *Revue Scientifique* is very interesting; the blood from a dog being injected into the blood-vessels of the head, the filling of the capillaries and the blush upon the face, with certain fibrillary contractions are very well described. The muscular excitability was very much increased after the transfusion, and an opening being made through the cranium by means of the trephine, the condition of the brain *in situ* was studied with more interest, both in connection with the capillary supply to the pia mater which was admirably injected, and with reference to the views of M. Luy's on the locomotion of the brain, which latter seemed to be in a measure confirmed by these observations.

Particular attention was paid to the study of the functions of the intercostal muscles, during respiration. The opportunity was a particularly good one, because the muscles were very well developed, and the muscular contractility was but little different from the normal condition. To render them very appreciable in their movements, the sternum was removed, then having laid bare the first five or six intercostal spaces, with their internal and external intercostal muscles, M. Laborde produced their isolated contractions by means of an interrupted current of moderate intensity.

1st. With the internal intercostal muscle each excitation and each muscular contraction caused invariably a depression of the superior portion towards the inferior. If the current was extended to several intercostal muscles at the same time, always restricted to the internal intercostals, a downward movement *en masse* of the side of the thorax was produced.

2nd. With the external intercostal muscle the same excitation produced constantly with the muscular con-

traction which followed, an elevation of the inferior portion towards the superior, the latter being held motionless by a light pressure of the fingers. And when the side was made motionless as when the scaleni act physiologically, an isolated current was passed through several of the spaces at the same time and acting upon the external intercostals, there was a synergic elevation *en masse* of the side and of the thorax.

These results were produced a great number of times in the presence of several physiologists, among them Professor Beclard, and even two hours after beginning the experiments the muscles still contracted very markedly. M. Laborde considers them as positively confirming the view that the internal intercostals are depressors of the walls of the thorax and consequently expirators; and that the external intercostals are elevators of the walls of the thorax and consequently inspirators.

MATERIA MEDICA AND THERAPEUTICS.

EPILEPSY TREATED WITH HYDROBROMATE OF CONIA.—R. Norris Wolfenden (*Practitioner*) gives the notes of seven cases of epilepsy treated by hydrobromate of conia with beneficial results. The medicine was given at first in half-grain doses three times a day, then increased to five-eighths of a grain, and in some cases, one and five-eighth grain doses were given twice daily for a week at a time. The drug failed where there were possibly gross lesions of the brain. The writer was induced to try it to avoid the unsightly eruptions following the use of bromide of potassium. The drawbacks to the use of the drug appear in the complaints of headache, and where in large doses, of giddiness, lasting for an hour after taking it, with sometimes a suffusion and congestion of the conjunctivæ. In the doses given, no cardiac or respiratory alterations were noticed. It is said that the dose of this drug must not exceed four and a half grains in twenty-four hours, commencing with one and a half grain. In this experience, a child of eight bore one and seven-eighths grain with only headache; a child of seven took one and a half grains per diem, without any complaint; two and a half grains per diem were taken by a female without complaint; one adult man took three and a quarter grains with impunity. In one case, two grains per diem caused sickness, headache, giddiness and "weakness" in a young man of eighteen. One and a half to two grains appears to be followed frequently by headache. Combined with constant application of the continuous current, Mr. Wolfenden has successfully treated a case of hemichorea with it.

MEDICINE.

ON THE DIAGNOSTIC INDICATIONS OF FREE HYDROCHLORIC ACID IN THE CONTENTS OF THE STOMACH.—Kredel (*Zeitschrift f. Klin. Med.*) and (*Edin. Clin. and Path. Jour.*) has made use of tropæolin, methytriolet and iron-chloride-carbolate to obtain color-reactions, indicative of the presence of free hydrochloric acid in the contents of the stomach, when

washed out about six hours after a meal. His cases had all well-marked gastric dilatation, finding that in carcinoma of the stomach there was almost invariably present free hydrochloric acid. He considers it as proven, that gastric carcinoma with dilatation of the stomach is thus marked out from gastritis dependent upon other causes, and that this test may be employed as a very valuable indication in doubtful cases.

THE SEPTIC PNEUMONIA OF NEW-BORN CHILDREN.—Silberman (*Deutsch. Archiv für Klin. Medic. and La Presse Médicale Belge*) gives the following conclusions:

1. The septic pneumonia of new-born and young children is closely associated with tracheobronchitis and should be regarded as a catarrhal pneumonia, or as a pneumonia from the introduction of foreign substances.

2. It is produced by the aspiration of the putrid amniotic liquid or the putrid genital secretion, or by the aspiration of air strongly charged with septic matter coming from the mother.

3. The disease is often complicated with affections of the pleura, but rarely with affections of the other organs.

4. The alveoli and the bronchi of children who have died with septic pneumonia are filled with numerous bacteria.

5. The blood of these children shows a remarkable abundance of leucocytes and a diminution or marked dissolution of the red blood globules.

6. Icterus is not a constant accompaniment to septic pneumonia.

7. Septic pneumonia shows itself in one to two days after birth.

8. A fatal termination is inevitable, in most of the cases it occurs on the third to fourth day of the disease.

9. The rapid penetration of septic substances into the lungs of new-born children, is favored by the incomplete closure of the glottis and by the shortness of the principal bronchus.

10. The great diffusion of the septic process in the lungs is favored by the metamorphosis of the epithelium and by the slight expiration of the newly-born, owing to the feebleness of their respiratory muscles.

SURGERY.

DEMONSTRATION OF BONE PREPARATIONS TREATED BY A CONVENIENT MODE OF MACERATION.—Partsch (*Beilage zum Centralbl. für Chirurgie and Edinburgh Clinical Journal*) recommends the following method:

The fresh preparations, freed as far as possible of their soft parts, are placed in a three to five per cent. solution of caustic soda kept at a temperature of from 80°–86° F. The solution is to be changed daily, and during the first week oftener if there is much of the soft parts and a medium quantity of solution. The soft parts swell up, and the fat dissolves and separates out on the surface of the fluid. The fluid is at first

discolored by the hæmoglobin, but after frequent changing becomes clear. No decomposition occurs, and when it has previously been present, it soon disappears, and the bad smell goes away.

In from eight to fourteen days even the muscular attachments soften and come away, and the bones may be removed from the fluid quite white and smooth, and showing the most delicate structure. They should lie for a few days in cold water, be wrapped in blotting paper, and allowed to dry slowly.

EXTRAORDINARY, AND PROBABLY UNIQUE, CASE OF STONE IN THE BLADDER.—Dr. Alex. Patterson, (*Glasgow Medical Journal*) gives, with a photograph, natural size of the stone, the account of a man, 44 years of age, who as a youth was a factory operative and fell at the age of 17 with his leg astride an iron bar, sustaining, among other injuries, a rupture of the urethra and laceration of the perinæum. Through the opening in the perinæum, as well as by the urethra, blood passed for a period of two weeks. Two attempts at closure of the perineal fistula were ineffectually made, and the urine continued to dribble without ceasing.

Twenty-seven years later a physician was called upon to relieve pain in the bladder, for the relief of which sedatives were prescribed; nothing abnormal was noticeable beyond the sinus in the perinæum. About three weeks later, at another visit, the sinus was seen to be considerably enlarged, and the patient requested the doctor to introduce his finger through the fistula, and he would feel the stone. On passing his finger through the opening, the Doctor at once felt the calculus, but his finger entered a large irregular cavity in the stone, and the patient explained the presence of this by saying that he had introduced a chisel, with which he attempted to break up the mass, and had managed in this way to remove about *one ounce*.

The Doctor started home for forceps, with which to remove the stone, but during his absence, whilst the patient was walking about his room in great pain, the stone suddenly burst the perinæum, and fell heavily on the floor, breaking in two pieces. When expelled, it weighed nearly 14 ounces and a half, which, taken with the portion removed by the chisel, makes 15½ ounces, which is, so far as Dr. Patterson can discover, about the heaviest stone on record in the annals of surgery, in which the patient recovered after its removal.¹ The stone measured in long circumference 10⅝, and in the short circumference 8½ inches.

The lacerated perinæum was dressed with carbolic oil, and six days from the date of the expulsion of the stone, the patient was attending to his business as usual. He died at the age of 55 years, eleven years after the passage of the stone, and of an apoplectic attack. During the intervening period he passed his water with difficulty, and was fully convinced that there was another stone in his bladder. His physician could not pass even a No. 1 sound into the bladder through either urethra or sinus. In addition to

¹Gross on the Urinary Organs, refers to Dr. Mettauer, of Virginia, as having in his possession a calculus of urate of ammonia, weighing upwards of sixteen ounces, which he removed by the lateral section, the patient making a good recovery.

the sinus, which never entirely closed, a cicatrix, three inches in length, existed in the perinæum.

CATHETERS AND SELF-CATHETERISM.—Dr. J. B. Mitchell, in the *Medical Press*, gives the results of two years' personal experience upon this subject. He dismisses the silver catheter of old times with but few words, the so-called gum elastic catheter with the wire stylet he considers may still be preferred in some cases by the practitioners, but in respect of cases wherein self-catheterism is practiced, the utility of that kind of instrument has entirely passed away. About a score of years ago, there came into notice a gum catheter without stylet, the surmounting of certain difficulties in the urethral passage being secured by means of a permanent bend implanted in the instrument (otherwise quite straight) at a short distance from the point. The best known of such catheters is the *condée*, so-called from the French word signifying elbowed or bent. It has the fewest inconveniences for self-catheterism, the manipulation required for its introduction into the bladder being slight and easily acquired. When irritation arises, that accident may be due to one or other of the following circumstances, or in some measure to all of them: (1) The *condée*, by the elbow room which it requires, gives rise to an increase of friction in its passage; (2) the eye of even the best made gum catheter presents edges calculated to ruffle the delicate mucous lining of the urethra, forced as it is at the constricted part, to dip into the hollow of the eye; (3) the "gum" material, which is dried linseed oil, being very readily acted upon by the oily or greasy lubricant wherewith the catheter, on being used, is smeared, after a certain amount of use, becomes sticky, thereby greatly adding to the friction.

Recognition of these inconveniences has led to the manufacture of catheters of mineralized India rubber. These instruments, which are extremely flexible, require no skilled manipulation; being quite straight there is no point of increased friction; the eye is hollowed out and the edges so smoothed down as to give rise to no ruffling whatever. (This is true, perhaps, of the English instrument only, the French India rubber catheter, for instance, being extremely defective—dangerously so in the eye). Resisting much better than "gum" the action of oil or grease, India rubber is much less liable to become sticky.

Dr. Mitchell here criticises the American catheter as furnished by Tiemann, by declaring that its fine polish deteriorates after being used a few times, either owing to the perishable nature of the rubber, or the effect of the London atmosphere upon it, and the substance of the catheter becomes brittle.

Within the last twelve months there has been brought out a gum instrument which may be looked upon as an imitation, in boiled linseed oil, of the India rubber catheter. It is straight throughout, and very nearly as pliable as that instrument. In two respects it certainly compares disadvantageously with the rubber catheter. The margin of the eye is not rounded off in such a way as to present no edge whatever to give rise to friction, while the material is very liable

to deterioration from grease. The stickiness which results from this deterioration cannot be correctly estimated by the fingers. Being developed by heat and moisture, it rapidly shows itself, however, in the urethra, becoming more and more apparent, within certain limits, the longer the catheter remains in the passage with the obvious result, which in some cases is very marked, of causing the withdrawal of the instrument to be attended with greater resistance than its introduction. There have been cases, indeed, wherein very great effort was needed to withdraw a gum catheter which had been passed down the urethra with comparative ease. It is very obvious that such an amount of dragging of the sensitive mucous lining of the constricted urethral canal must be productive of irritation with more or less of consecutive mischief.

To keep a catheter smooth and free from stickiness, some lubricant must be used that could be easily acted upon by a solvent incapable of attacking India rubber. Castor oil proved a very superior lubricant, but when submitted to the action of alcohol it was only partially removed from the catheter. Absolute alcohol would remove it, but was expensive and not easily obtained. Sulphuric ether was expensive and attacked the rubber. Pyroxytic ether picks up castor oil in a surprising manner. After exposure to its action for an hour or two in a tube, an India rubber catheter, smeared inside as well as outside with castor oil, on being withdrawn and then dried, was found to be as clean and smooth as it was before use.

The consistency of castor oil allows of a large measure of extra lubrication. When a certain quantity was, by exhaustion at the superior orifice of the catheter, sucked into the tube of the instrument, it did not at once seek to escape, but kept its place till the constricted part of the urethra was reached; here pressure of a stripping character exerted between the finger and thumb, in a downward or inward direction, upon the extruding upper end of the instrument, by expelling the oil wherewith its opposite end was charged, flooded the urethra with lubricant at the constricted part, and bore along, as it were, the catheter point through the prostatic rapids, landing it safely in the bladder. Subsequent experience has abundantly shown that the flooding, when copious, is always completely effectual in the shooting of the urethral narrows.

CORRECTION—*Number 4, Vol. 3, July 26.*—By a simple omission to change the *number and date*, in the standing part of the first outside page of the JOURNAL of July 26, in making up the form, the whole issue was printed and mailed bearing the same number and date on the outside title-page as the previous issue. This has led some of our readers to conclude, without looking further, that they had received two copies of No. 3, July 19, and no copy of No 4, July 26.

If each reader will note the table of contents or turn to the number and date of the first page of reading matter, he will see that he has the right number of the JOURNAL, and by correcting the number and date on the outside with his pencil, he will not be troubled in making future references to his file.

THE
Journal of the American Medical Association.

PUBLISHED WEEKLY.

THE EDITOR of this JOURNAL would be glad to receive any items of general interest in regard to local events, or matters that it is desirable to call to the attention of the profession. Letters written for publication or containing items of information, should be accompanied by the writer's full name and address, although not necessarily to be published. All communications in regard to editorial work should be addressed to the Editor.

SUBSCRIPTION PRICE, INCLUDING POSTAGE.

PER ANNUM, IN ADVANCE..... \$5.00.
SINGLE COPIES..... 10 CENTS.

Subscriptions may begin at any date. The safest mode of remittance is by bank check or postal money order, drawn to the order of the undersigned. When neither is accessible, remittances may be made at the risk of the publishers, by forwarding in REGISTERED letters.

JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION,
No. 65 RANDOLPH STREET,
CHICAGO, ILLINOIS

SATURDAY, AUGUST 9, 1884.

THE "ENGLISH METHOD" OF PERINEAL PROTECTION.—The prevention of perineal lacerations constitutes one of the most important advances in the art of midwifery. Adequate methods are of recent origin. Some years ago, Wigand, Meade, Jörg, Ritgeu, and in part Scanzoni, declaimed most vigorously against the act of "meddlesome midwifery." At the present day, however, accoucheurs do not affect this disregard for measures, whose object is the preservation, in an intact condition, of the female perinæum. Still, few general practitioners are disposed to value such prophylactic procedures as highly as a due regard for the physical welfare of their patients demands. Few medical gentlemen, for example, would agree with Hecker's *dictum*, that "the protection of the female perinæum is the most delicate, difficult and important function of the accoucheur."

As the resultant of many years' patient observation, experiment and discussion, a method of great efficiency has been developed, and is extensively practiced in Europe. For convenience of description, Carl Braun has designated it the "English Method." By Josef Spaeth and Gustav Braun it has been termed the Vienna Method, while Spiegelberg is of the opinion that the measure is of Teutonic origin. Charpentier, with characteristic patriotism, ascribes the procedure to Depaul. The important conclusion to be drawn from this diversity of opinion as to the origin of the method, is that the same general mode of prophylaxis of perineal tears is practiced in Austria, Germany, England and France. A universal proposi-

tion, in this connection, is not formulated. Schroeder, for example, adheres to the opinion expressed in the first edition of his book, that the kneeling posture, an exact imitation of the position assumed by the cow, is the physiological attitude of the parturient woman.

Certain French accoucheurs continue to follow the precepts of Louyse Bourgeois.

The object of perineal protection is to cause the neck to be the pole of the extension movement around the symphysis, and at the same time to retard the passage of the head, so that the elasticity of the perinæum is fully developed, the vaginal os completely dilated, and the anterior portion of the perinæum can retract over the face.

The left lateral position is most convenient for the patient and the accoucheur. The parturient woman lies upon her left side in such a manner that her head, approximated to the chest, is turned towards the left edge of the bed, while the pelvic extremity is directed to the right edge of the bed. The left lower extremity is extended, the right, with knee-joint semi-flexed, is separated from its fellow by a pillow, or better, an attendant. The accoucheur sits on the right edge of the bed, behind his patient, passes his left hand over her abdominal surface, between the thighs, and applies the palmar surface of his fingers to the advancing segment of the foetal head, to control the rapidity of its passage, and cause the neck to engage under the sub-pubic surface, as the pole of the extension movement.

The right hand is placed upon the perinæum (only during a pain) in such a manner that the thumb is laid along the right *labium majus*, the index and other fingers rest behind the left *labium majus*, while the volar surface of the hand covers the distended perinæum. The edges of the *labia* and the anterior edge of the perinæum are uncovered. In the pause between contractions, the accoucheur remains passive. In the beginning of a contraction, no pressure is made upon the perinæum, and the head is allowed to advance as far as the circumference of the vulvar orifice and the distensibility of the perinæum will admit. When the acme of the contraction is reached, both hands assume their respective positions, and guard the further progress of the head.

When the pains become violent, the abdominal muscles contract powerfully, and the woman throws herself about restlessly, the accoucheur fixes the pelvis between his arms,—or better, between his left arm and thorax,—presses the advancing occiput backwards, that is, keeps up *flexion*, while the right hand assists the manœuvre, by pressure against the sinciput. By slow, frequent advances, the cephalic

segment dilates the vulvar outlet, and develops the elasticity of the perineal structures. Little by little, the occiput and parietal protuberances pass beyond the plane of the vaginal os and the foetal neck is applied to the sub-pubic surface. Now is the time of greatest danger. The woman opens her mouth, cries out, and renders the auxiliary forces inoperative. In the pause, between two pains, the right hand, by moderate concentric pressure on the perinæum against the forehead, forces the head in the direction of the pubic arch, so that the child's chin is still approximated to the chest. In this manner, after the maximum dilatation of the vulvar os and development of the elasticity of the perineal structures, the foetal head is caused to present with its smallest diameters and circumference. *Sub-occipito-bregmatic*, *sub-occipito-frontal*, and *sub-occipito-mental* diameters and circumference, dimensions approximating the smallest possible vertical measurements, are substituted for occipito-bregmatic, occipito-frontal, occipito-mental diameters and circumference.

It must be distinctly borne in mind, that, under certain definite conditions, the preservation of the female perinæum in an intact state, is an impossible task. Some of these conditions are acquired *atresia* and organic stenoses of the vaginal os. Under these circumstances, episiotomy, an operation defended by Eichelberg 1850, Scanzoni 1852, Ritgeu,—is indicated.

The *constrictor cunni* is divided on either side of the *Labia majora*, in the direction of the ischiatic tuberosities, to the extent of four or five millimetres.

Mere verbal analyses and descriptions convey but an imperfect idea of the method here indicated.

Observation of the midwives in the Vienna General Hospital in the exercise of their truly wonderful manipulative skill, and actual practice under their direction, would give a more adequate conception and secure a more perfect mastery of this operative procedure.

The "English" method of perineal protection, thus briefly recounted, presents important points of difference from the method of Dr. James D. McGaughey, of Wallingford, Conn., ably sketched in the June number, current year of the *The American Journal of Obstetrics*.

GUMMA OF THE AURICLE.—Gumma of the auricle is certainly not often met with, in the absence of other syphilitic symptoms existing at the same time. Yet there is no reason, in the nature of things, why the ear as well as any other region of the body should

not be so affected. One such case having occurred in the practice of Dr. Hessler, of Halle, is summarized in the *Annales des Maladies de l'Oreille, du Larynx, etc.*, July, 1884.

The affection began as a swelling in the concave part of the auricle of right ear. It grew very large, the swelling extending to the posterior part of the ear and the mastoid region, obliterating even the angle at the back of the ear. It was of a red color at first, and then became livid. It was so painful that sleeping on that side was impossible. It is said to have suppurated for a few days, and then to have healed of itself. Although the swelling was so great, the meatus, although somewhat swollen, remained open, and the hearing was not impaired.

The man confessed to have had syphilis and to have been treated for the same, and the sore looked syphilitic, but in the absence of other symptoms on the body, it was not thought desirable to institute syphilitic treatment (!!!).

He was, consequently, treated with various washes, caustics and baths for six months, to no effect. Finally a swelling appeared on the tibia, which was readily recognized as a syphilitic node; and on the administration of the iodide, without other treatment, the swelling on the ear disappeared.

SULPHUROUS ACID IN OBSTINATE OTORRHOEA.—In the *Annales des Maladies de l'Oreille, du Larynx, etc.*, July, 1884, Dr. Woakes, of London, speaks very highly of the use of sulphurous acid in the treatment of those obstinate cases of otorrhœa which resist the use of boric acid. He refers to such cases as are associated with a certain roughness of the bony structures situated anywhere in the track of the discharge, whether in the external meatus, the annulus, the small bones of the ear, or the inner wall of the middle ear. He does not, of course, include such cases in which the necroses affect extensive parts of the temporal bone.

The strength he uses is one part dilute sulphurous acid (B. P.) and three parts water, which, after cleansing the ear, is to be warmed and poured into the meatus, and retained there for half an hour. The application is made three times a day. He recites two cases in support of his statement, but adds that he has used it for five years, and that the method has now become with him a routine practice. He adds that later experience has shown him that the prior removal of the granulations is not necessary, except in those cases in which the granulations are so exuberant as to obstruct the acid from the affected bone.

SUCCESSFUL OPERATION FOR DETACHMENT OF THE RETINA.—Dr. McGregor Robertson, of the Glasgow Ophthalmic Hospital, reports a case in the service of Dr. Wolfe in which complete detachment of the retina was successfully operated upon. The trouble is said to have begun about two years ago, and at the time referred to the blindness was complete. "He could not see the light of a lamp held before him in any direction." The operation consisted in laying bare the sclerotic by incising the conjunctiva and sub-conjunctival tissues, and then "puncturing" (query incising) the sclerotic in the line of the vertical meridian. In the instance recorded, the operation was performed twice, the second time at an interval of about six weeks from the first. The first operation is said to have afforded vision only in the outer half of the normal field, whilst the second operation is said to have restored the function of vision for the whole field. In the first operation a suture was used to unite the conjunctival wound, in the second no suture was used. According to the report which comes from the *British Medical Journal*, May 3, 1884, the patient could finally read Snellen's type 20 at a distance of 15 inches. Dr. Wolfe claims special advantage from the dissection of the conjunctiva and sub-conjunctival tissue before penetrating the sclerotic.

SOCIETY PROCEEDINGS.

GYNÆCOLOGICAL SOCIETY OF BOSTON.

Regular session, January, 1884.

The Society met for its annual meeting—the 16th year of its existence—upon the second Tuesday of January, and organized soon after 4 o'clock P. M. H. O. Marcy, M.D., was elected President, A. L. Norris, M.D., Vice President Henry M. Field, M.D., and W. S. Brown, M.D., were severally re-elected as Secretary and Treasurer, and H. G. Harriman, M.D., was appointed Assistant Secretary. The committees of last year, upon membership, etc., held over.

Wm. G. Wheeler, M.D., the retiring President, having positively refused a re-election, in accordance with the requirement of the constitution of the Society, presented his annual address, his subject being, "A Question of Modern Wound-Treatment." The reader proposed in his remarks to illustrate a text from Ecclesiastes,—“That which hath been is now, and that which is to be, hath already been.” A brief digest of the address follows.

Allusion was first had to the old-time treatment of subcutaneous wounds, and to what was indeed a practical antiseptic treatment centuries before Lister and his system was born. The strong styptics, then in use, and the actual cautery were as effective hæmostatics as was Ambrose Pare's ligature; and the heated

pitch, with which leaking wounds and stumps were hermetically sealed, opposed as real obstacles to the entry of germs as anything that Lister has proposed.

The aspect which modern wound-treatment presents was first observed from the standpoint of ovariectomy and the removal of fibroids and tumors from the peritoneal cavity. Bryant, of London, Thomas, of New York, and others were quoted to the effect that the condition variously called puerperal fever, and otherwise must, of necessity, imply the absorption of a poison into the blood. The laceration of the cervix, or of whatever part involving lesion of the mucous membrane, provides the open door; while the personal diathesis affords both soil and pabulum for future development. Here the reader paused for a moment to direct attention to the analogy existing between natural labor and a capital surgical operation. Look at the laceration of capillaries, veins, lymphatics, etc., at the placental site. It is not the result from operations done under a cloud of spray, but it is like a subcutaneous or submural wound, inflicted in the dark and, as it were, in nature's vacuum.

The earlier ovariectomists seldom allude to blood-poisoning as a sequel to their operations. Peaslee, in his work, reports six or seven cases treated by his method of drainage. Later, Sims proposed drainage through Douglass' fossa. He holds, by the way, the opinion that septicæmia may develop in a few hours, and death therefrom follow twelve to forty-eight hours after the operation. While approving of the drainage-tube in the main, the author was not sure that through this avenue even septic material might not, exceptionally, enter the system.

Dr. Wheeler further contended, 1st, that blood-poisoning may, and does, complicate low forms of disease; 2nd, that it is often a complication of ovariectomy, and a more frequent cause of death than was formerly supposed; 3rd, blood-poisoning increases the hazard, and has been properly considered a bar to surgical interference, with extra and intra-uterine fibroids.

Detailed reports of three cases closed the paper; the corresponding specimens being presented to the Society. The first was a uterine polypus of fibroid character. Septicæmia followed the operation, and recovery was very slow. In the second case—one of intra-uterine fibroid of size of a duck's egg—pyæmic poisoning complicated the effort at extraction, and death followed in fourteen days. The third case was of a monocyst, ovarian in character, of about three years' growth. Firm and extensive adhesions complicated its removal. On the fourth day septicæmia set in, which pursued a rapid course till the patient became comatose. On the eighth day from operation a foetid fluid was evacuated by means of a catheter, and the traumatic cavity washed out. Thereafter the patient seemed as if brought back to life, and made a gradual recovery. In this case, as in the others reported, many points of interest have been omitted for want of space in making an abstract.

On call for pathological specimens, Dr. J. G. Pinkham, of Lynn, presented, with promise of fuller statement upon some future occasion, first, a uterine

polypus, probably myo-fibroma, of size of average white potato. A second specimen came from a suppurating ovary, which the doctor had removed last October, presenting one large cyst and several smaller ones. This specimen had not been disturbed since its removal, having been kept in a mixture of alcohol and carbolic acid. Had meant to bring, also, a specimen of the accompanying fluid, fifteen to twenty pounds of which had been drawn off. It was of a thick, pea-soup character, containing a yellow sediment apparently largely made up of pus cells, supernatant liquid being transparent and looking like glue.

Dr. A. P. Clarke asked about the fibroid. Reply: It came away spontaneously at last. Patient had consulted Dr. Warner, of this Society, 10 years ago, and, having profuse and exhausting hæmorrhages four years later, had then consulted himself. Had expected to do nothing beyond palliation. Last February she began to have expulsive pains, which still continuing at intervals, in July Dr. P. proposed and did an operation. Patient at present has symptoms which look as if another tumor was forming.

In reply to further questions, Dr. P. continued: The tumor was removed by *ecraseur*. It being hard to pass the chain, he resorted to a modification of the usual instrument, consisting of an apparatus of copper wires and fish-line, which he described. The mass so filled the vagina that it was very difficult to get at the upper part of the tumor and its attachment.

Dr. Wheeler remarked on the great trouble in such cases in getting the chain around the pedicle, as was necessary to be done for the success of the operation.

Dr. Nelson remembered that Dr. Marcy had previously shown the specimen of a uterus removed by abdominal section. He (Dr. N.) would now offer to the consideration of Fellows slides containing microscopic representations of this part removed by frozen section, which specimens were duly examined and discussed by gentlemen present.

The committee appointed to prepare and present resolutions expressive of the loss sustained by the Society in the recent death of Dr. Marion Sims, an early honorary member, and the eminent respect in which he was held, hereupon reported, and upon vote, the resolutions were declared approved, and the Secretary was instructed to have them properly written out, that a copy might be sent to the family of the deceased.

Dr. W. S. Brown was hereby led to remark upon the eminently democratic character of English medical societies. On the other hand, and by strange and unexpected contrast, American societies were prone to be exclusive. The late Dr. Sims was everywhere and always an enemy to exclusiveness; he would make all medical organizations of that democratic character that is in keeping with our political institutions. This was his original and constant policy, and most earnestly urged upon its management in the formation of the American Gynecological Society, but his policy did not prevail.

The annual report of the Treasurer showed the Society to be in prosperous condition pecuniarily. The annual lunch was then discussed, after which Society adjourned.

CHICAGO MEDICAL SOCIETY.

Stated meeting, July, 1884. Dr. D. A. K. Steele, President; Dr. L. H. Montgomery, Secretary.

The meeting was well attended, and the papers read and cases presented were interesting and important. But owing to the crowded state of our columns at this time, we are constrained to greatly abridge the report which the Secretary has kindly furnished to us.

The first report was in reference to a case of pyosalpinx, by Dr. Franklin H. Martin. The patient was a married woman, aged 27 years, weighing 200 pounds, never having borne children, but had one abortion at three months, four years since. Little more than one year since she began to complain of morning sickness, some enlargement of her breasts, pains in her back, and other symptoms which caused her to think she was pregnant, although she continued to have a moderate menstrual flow at each regular period. After several examinations without making a satisfactory diagnosis, the patient was anesthetized, and the contents of the pelvis and abdomen thoroughly examined.

The uterus was found of small size, and closely pushed against the neck of the bladder and pubes by a tumor of considerable size occupying the posterior peritoneal cul-de-sac. But the nature of the tumor was not satisfactorily determined. The patient, however, continued to suffer so much from pain in the back and sickness, that Dr. Martin undertook an operation for the removal of the tumor by abdominal section, as in ovariectomy.

After entering the abdominal cavity the tumor was found to consist of a great dilatation of the left fallopian tube, the walls of which were so thickened as to render fluctuation obscure, but a needle puncture proved the contents to be purulent. The exterior of the tumor, however, was so extensively adherent to the intestines and adjoining parts as to render its removal impracticable. Consequently, Volkman's method was adopted. The anterior wall of the tumor was stitched to the peritoneal edge of the lower part of the abdominal incision for a distance of about three inches, and this part of the wound left open, while the rest was closed with sutures and covered with antiseptic dressings. In a few days, adhesions having taken place between the tumor and the peritoneal margin of the wound, the former was freely opened and a large quantity of pus discharged. The cavity was washed out with a 2 per cent. solution of carbolic acid, free drainage maintained, with antiseptic dressings, and the patient made a good recovery. Some remarks were made in regard to the case and its management, by Drs. J. H. Etheredge, H. P. Newman, A. H. Burr, and L. L. McArthur.

Dr. S. W. Wetmore read a paper on "The Rational Treatment of Fracture of the Clavicle," illustrating it by adjusting his appliances to an assistant. The writer presented nothing new, but gave good descriptions of the methods devised and practiced by Drs. E. M. Moore, of Rochester, N. Y., and Lewis A. Sayre, of New York, respectively, making judicious comments on their relative advantages and dis-

advantages. The paper elicited remarks from Drs. R. W. Bishop, C. E. Webster, W. L. Axford, D. A. K. Steele, A. B. Strong, L. H. Montgomery, and W. H. Curtis.

The remainder of the evening was occupied by Dr. Jefferson Bettman in the reading of a carefully prepared paper on "Rhinolithiasis," embodying an interesting case which had occurred under the observation of the writer. As the paper will soon appear in full in this journal, it is not necessary to give an abstract here.

After some remarks by Dr. F. O. Stockton, the Society adjourned.

MASSACHUSETTS MEDICAL SOCIETY.—PROCEEDINGS OF THE SUFFOLK DISTRICT MEDICAL SOCIETY.—ADJOURNED SPECIAL MEETING.

SECTION FOR CLINICAL MEDICINE, PATHOLOGY, AND HYGIENE.

ALBERT N. BLODGETT, M.D., SECRETARY.

May 21, 1884. Meeting called to order at eight p.m., Dr. R. T. Edes in the chair.

The Secretary read a communication which he had received from the Boston Society of Arts, inviting this society to attend a meeting of that body at the Massachusetts Institute of Technology to listen to a description of the system of heating and ventilation which has been adopted in the New Building of the Institute, and which possesses many points of interest, some of which are novel.

The chairman then introduced the subject for this meeting, which was the continuation of the discussion upon the Eputation of Sewage by Irrigation and Agriculture. See Journals for July 26, and August 2, 1884.

Mr. Eliot C. Clarke was first called on, and spoke as follows: "Much has been said lately of the successful disposal of sewage at Pullman, Ill., by land irrigation. It affords almost the only instance in which it is claimed that pecuniary profit has attended such a method of disposal. I have recently visited this sewage farm, and the result of my observations there may be interesting to the Society.

Land irrigation was adopted at Pullman, not with the hope of profit, but from necessity, there being no other practical means of getting rid of the sewage except at enormous expense. House sewage only, of which there is a daily supply of about 200,000 gallons, is disposed of by irrigation. Rain and water used for mechanical purposes are not mixed with the sewage proper but are discharged into Calumet Lake.

The whole sewage farm consists of 1,500 acres of flat prairie, situated within two miles, or less, of the town. Of this area, however, only 150 acres were used last year in purifying and utilizing the sewage, the remainder being held for future use, or cultivated without the application of sewage. The soil is a rich loam underlaid by sand. The portion to which

sewage is applied is all underdrained by pipes about six feet below the surface. About ten acres are prepared as filter beds, being more carefully underdrained than the rest, and this tract disposes, by filtration, of the sewage at such times as the crops need none or would be injured by it.

The crops to which sewage is furnished are chiefly celery, cauliflower, cabbage, and other kinds of garden produce which flourish with a copious supply of water. The sewage is only applied to them at such times and in such quantities as is beneficial, principally in the morning and evening, during dry weather. Some crops, as potatoes, never receive any sewage since it is found to injure them. The superintendent, Mr. Martin, thinks he gets earlier and better vegetables than he would from land that was not irrigated. He also believes (without special opportunities for comparison) that the crops do better with sewage than they would if simply irrigated with pure water, that is, that the sewage acts somewhat as a manure. It is evident, however, that it does not act as other manures do since he finds that it injures his land to apply sewage to it longer than for one season. After one season's application the sewage should be omitted for one year and the land, instead, enriched with barn-yard manure.

The profit last year from sale of crops grown on that portion of the farm irrigated with sewage was about \$5,000. The superintendent thinks that, had it not been for early frosts, the profit would have been \$7,000. In calculating this gain, however, no charge was made for rent of the land or for interest on the cost of draining and otherwise preparing it, or for the machinery and other plant necessary to raise and convey the sewage to the farm, or for fuel and attendance on the pumping engines. These items would have largely exceeded the calculated profit, so that had it been possible to discharge the sewage by gravity into some neighboring body of water it would have been much cheaper to do so.

Under the circumstances the result is very satisfactory. The town gets rid of its sewage without creating any nuisance. No trouble has been experienced in winter. During very cold weather an inch or so of ice forms on the surface of the filter beds, but the ground beneath remains open and the sewage soaks away. Thus the primary object of the farm, which is to get rid of the sewage at all times, is satisfactorily accomplished, and, in addition, the land is cultivated, and the value of the crops produced exceeds the cost of cultivation.

While the result at Pullman is encouraging for those towns which are compelled to purify their sewage on land, there is nothing in it to commend sewage farming to towns which can discharge into water without doing any harm thereby. The conditions for sewage farming would rarely be so favorable as they are at Pullman. At that place a comparatively small amount of sewage is to be disposed of, and close at hand is available an abundance of cheap but rich farming land, perfectly flat, and with soil especially adapted to the purpose.

In Boston the territory south of Charles river fur-

nishes, in dry weather, one hundred times as much sewage as Pullman. If the same ratio between acreage and sewage were preserved, Boston would need a farm of 15,000 acres, an area as large as the city proper, South Boston, Dorchester, Roxbury, Brookline, and Brighton. It is needless to say that no such area suitable for the purpose can be found within accessible distance.

The sewage of Pullman is about three times as dilute as Boston sewage, but otherwise appears to be of the same material. It is allowed to flow on to the land each morning and evening unless rains occur, when it is not used so frequently.

The effluent water is clear and free from smell or taste, and fish are found at the outlet of the filter beds, which is considered possible only in pure water. At the opening of the sewers there is a perceptible odor, but it is the smell of fresh sewage, and not that of decay or decomposition. The superintendent of the farm resides at a short distance from the filter beds, and suffers no inconvenience from their proximity to his dwelling, and his family have never been afflicted with any disorder attributable to that cause. The centre of the farm is between one and two miles from the centre of the city.

Dr. Faxon stated that he had listened with much satisfaction to the discussion, but that one element existed in American sewage which was not found in that of any European system. The sewage of every American city is loaded with tons of grease, which materially interferes with its utilization in the same manner as is followed in other countries. The greasy contamination forms a solid crust in the upper layers of the soil, which the roots of plants cannot penetrate. The Pullman farm is far from representing the actual results of such a system in its more extended adoption. The sewage from Boston is at present discharged into tide-water, but the nuisance of sewage pollution is not removed. A certain portion of Boston sewage comes to the shores of Quincy Bay, and is already creating a nuisance along the beach in that vicinity. From the windows of the Sailors' Home at that place can be seen a layer of sewage many acres in extent upon the surface of the water between that point and the neighboring islands. As summer approaches the sludge becomes more abundant, and is thrown up on the shore, where its stench becomes intolerable. Some other method than the present must ultimately be adopted for the disposal of the sewage of Boston.

If an engineer were requested to designate a perfect system of sewerage it is quite impossible to say what method would be recommended, but at present, everything taken into consideration, filtration seems to be the most available method known.

In reply to Dr. Faxon, Mr. Clarke said: "This is the first intimation I have had that the sewage works at Moon Island create any nuisance or are likely to. Those who live on the island experience no discomfort. I have seen some sludge about the outlet, and there are places on the works where one can get the odor of sewage. That was to be expected. The sewage which is discharged at Moon Island formerly emptied at fifty outlets in Boston, and made fifty nuisances

close to residences, places of business, hospitals, bath-houses, etc. It has not been changed to cologne water by being diverted to Moon Island. But I do not believe that any nuisance will be created there which can possibly effect any one not living on the island.

Although a little of the sewage may deposit near the outlet, almost all of it goes out of the harbor. It follows an unvarying course between Long and Rainsford Islands, and none of it ever turns into Quincy Bay. Its outward course can be distinctly traced for about a mile, but at a little greater distance from the outlet the dilution with salt water is so great that all trace of the sewage is lost.

Dr. Marcy inquired of Dr. Faxon the reason why he believed the fatty matter of sewage caused the soil to mass together and thus, as stated, prevent the penetration by the rootlets of plants. Dr. Marcy questioned if this could really be true since the fatty materials of sewage are chiefly animal, and it is well known that these rapidly and easily undergo fermentation and decomposition, setting free the fatty acids at ordinary temperatures. Thus these compounds taken to pieces by the action of the bacteria and fitted to serve as plant food. Dr. Marcy inquired as to filtrative power of the soils as shown in the experiments of Dr. Faxon and at the Woman's Prison, saying we must bear in mind that for about six months of the year in our latitude there is very little vegetation, and provision must be made for winter sewage. Contrary to the usual belief, sand makes a most unreliable filter.

Mr. Edward S. Philbrick, C.E., spoke as follows: The subject under discussion is a very broad one, and I shall therefore limit myself to the question of applying the sewage of Boston to irrigate the soil. While not wishing to be understood as opposing the system of irrigation by sewage in general, and while recognizing the importance of making strenuous efforts to prevent the pollution of water supply by a reckless discharge of sewage into natural water courses,¹ I will refer to some of the obstacles which tend to render sewage irrigation a difficult plan for this city.

The money value of the solid and dissolved ingredients of sewage has been urged by many persons who have investigated the subject. Many skilled investigators have devoted their attention to this question, particularly in Europe, within the past ten years, and we have much information from that source as from the experiments made by European towns in the disposal of their sewage by irrigation.

But the money value of the ingredients of sewage is by no means the only questions of importance in the consideration of its disposal. It has often been found in developing mines that the number of pounds of copper or silver in a ton of ore, as determined

¹It seemed to me that Dr. Barnes has informed himself chiefly by *reading*, and that his reading has embraced only one side of a question which has been attended with a very warm *partisan* discussion in England lately. I hope its discussion here may be more deliberate and of a broader character. One thing is certain in my mind, namely, that it is a *local* question very largely, and that *patent systems* are no more likely to be widely applicable in our profession than in your own, and for similar reasons.

in the laboratory by assay, is but a poor guide in deciding upon the value of the ore or the mine. We must also know what it costs to stamp, wash, smelt the ore and refine the metal that exists in that ore before its commercial value can be established. So in the disposal of sewage by irrigation it has often been found impossible to recoup the cost of the process by the product of the farm. The disposal of the sewage in some *innocent* way is necessary to the welfare of the community, so that for sanitary reasons such a course may often be the very best, though no source of profit, simply because it is the cheapest way of getting rid of a dangerous material; but it should not be regarded as likely to be *profitable* as a commercial undertaking, except under the most favorable circumstances.

The difficulties met with are such as these: Plants that are useful as farming products do not tolerate a constant saturation of the soil they grow in. Therefore a sufficiently large area of soil must be treated to allow of applying the sewage on alternate fields, so that one may be receiving it while it is soaking away on the other. Even then we find that the plants which need a copious supply during a certain stage of their growth need much less at other stages when approaching maturity. We find, too, that the crops which are benefited by a large quantity of fluids in a dry month would be destroyed if an equal amount were put on the land in a rainy month. Now since the flow of sewage from any city is likely to be rather more copious in a rainy period than in a dry one, even though pains may be taken to exclude the rainfall from the sewers, the crops are often drowned with sewage at one time while getting barely enough to supply their wants at another. For this reason those sewage farms have been most successful where the farmer was not obliged to take the *whole flow* but merely what he desired from time to time.¹

In order to make sewage irrigation successful the land must be located favorably, must not be too steep in its declivities, and must be had at low rates of cost, that is, consistent with prices paid for other farm lands. Such a surface is not easily found near Boston.

However great the advantages of irrigation may be to certain crops, it is not so applicable to hoed crops as to the grasses, for the reason that irrigation puddles the surface, which unless very sandy, cakes and hardens when drying, requiring frequent hoeing to pulverize the soil. Therefore it has been found that Italian rye grass is the best crop for sewage irrigation. But this is a crop which is poorly adapted to our climate and is of little value except for soiling cattle. Moreover we have in this climate at least six months of every year when no such crop can be grown, while the flow of sewage is continuous during the year.

(To be continued.)

¹The success of the Gennevilliers sewage farms, as I am informed, is attributable to this fact, that the delivery of sewerage to the farmer was at his option and not obligatory. Such a system can never be a reliable source of relief to a town so long as any considerable portion of its sewage flow is liable to be left undisposed of in a wet day.

STATE MEDICINE.

MICHIGAN STATE BOARD OF HEALTH.

Reported for the JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION.

The regular quarterly meeting of the Michigan State Board of Health was held in the office of the Board at Lansing, Mich., July 8, 1884, the following members being present: John Avery, M.D., of Greenville, President; C. V. Tyler, M.D., of Bay City; Henry F. Lyster, M.D., of Detroit; J. H. Kellogg, M.D., of Battle Creek; Victor C. Vaughan, M.D., of Ann Arbor; Arthur Hazlewood, M.D., of Grand Rapids; and Henry B. Baker, M.D., Sec'y.

The Secretary presented a report of four outbreaks of cheese-poisoning in Michigan during May and June, namely, at Middleville, Barry county, Jerome and Jonesville, Hillsdale county, and Big Rapids, Mecosta county. All persons who ate of the cheeses were taken sick, (in all about one hundred and sixty-four persons), with the same symptoms, i.e., pain and burning sensation in stomach, intense vomiting and purging, feeble pulse, cold extremities, and tendency to collapse. All finally recovered. The cheeses were ordinarily good looking samples, but when cut or broken a liquid oozed into the pores. In each case the cheese was made at the factory of G. B. Horton, Fruitridge, Lenawee county, Mich.

Dr. V. C. Vaughan, committee on foods, also read a report on cheese-poisoning. At the request of the Secretary, he had visited the factory at Fruitridge, and had analyzed specimens of the cheese. Everything about the factory appeared to be scrupulously clean, and nothing in vats, cans, or surroundings offered any explanation of the cause of the poisoning. Analysis showed no arsenic, copper, lead, iron, or other mineral poison. When the cheese was cut or broken, a whitish liquid oozed into the pores, and in this liquid microscopic organisms were detected. The liquid was very strongly acid. For more than 100 years the attention of the scientific world has been drawn to the subject of cheese-poisoning by repeated outbreaks of this sort in this country and in Europe. Much has been written on the subject, and many investigations carried on, especially in Germany. It has been variously ascribed to diseased milk, decomposition and the development of certain fatty acids, etc., but we do not yet know what makes the cheese poison. The manufacturer said the cheese which produced the ill results, was all made between April 26 and May 26, 1884. It was made in the same manner and with the same care as other lots which had given no cause for complaint. Good cheese is only very slightly acid, and slowly reddens blue litmus paper. The poisonous cheese was intensely acid, instantaneously reddening blue litmus, when the paper was applied to the freshly cut surface. This test for poisonous cheese appears to be practicable. The blue litmus paper could be applied by any grocer to each freshly cut cheese. If the litmus paper is instantly turned red by the liquid which oozes into the pores, the cheese is to be suspected as poisonous.

Dr. Vaughan's report will be published in the next annual report of this Board.

The Secretary reported that small-pox was brought into Rose Lake township, Osceola county, Mich., June 9, 1884, by a German immigrant who with wife and three children, landed in New York, June 4, by steamer "Weser," "Weiser," or "Wieser." The immigrant says that on the passage over, there were on that vessel three deaths from small-pox, and several cases that recovered. The immigrant was taken sick June 13, and was attended by Dr. Bettes, of Le Roy village, in the adjoining township of Le Roy, who could not know the true nature of the disease till the eruption took place, soon after which Dr. Bettes himself came down with the disease and has since died. The health authorities of Le Roy village had neglected to appoint a health officer as the law requires, because they thought they would "save a health officer's salary by doing without one." Dr. W. J. Law was then appointed health officer and he seems to have done very efficient work, as did also Mr. Bryan Monaghan, health officer of Rose Lake township. The townships of Rose Lake and Le Roy united in the construction of two hospitals, which were built June 29. At last report there were ten (10) cases in the hospitals, five cases at Tuston, and one at Cadillac.

This outbreak is another illustration of how Michigan and the Northwest suffer from a lack of a careful immigrant inspection service, such as was planned by the National Board of Health, and for a time carried on, but discontinued for want of an appropriation.

The chairman of the special committee appointed to examine the sanitary condition of Washtenau and Jackson county jails, read their reports which were ordered printed in the annual report of the Board for 1884.

Owing to the spread of Asiatic Cholera in Europe and the liability of its introduction into this country at any time, it was decided to issue a circular to local Boards of Health on the prevention and restriction of cholera.

The next regular meeting of the Board will occur Oct. 7, 1884, instead of the second Tuesday in Oct., which would be its regular time.

FOREIGN CORRESPONDENCE.

PARIS LETTER.

PARIS, July 4, 1884.

Dr. Debove has recently introduced a new treatment for simple ulcer of the stomach, based on the pathogeny and the anatomical lesions of this affection. Simple ulcer of the stomach was for a long time considered to be of a tuberculous origin, then cancerous, typhic, and even dysenteric. Later on, it was attributed to inflammation of the mucous membrane of

the stomach, which opinion was evidently more correct than the preceding. Finally, Rokitsanski enunciated a theory which is now in vogue, as it better explains the nature of the disease, and thus leads to a more rational system of treatment. According to Rokitsanski's theory, the ulcer in the stomach would originate in the disturbance of the circulatory system in a circumscribed portion of the mucous membrane of that organ, which would weaken its vitality to such a degree as to allow itself to be destroyed by the gastric juice. The form of the circulatory trouble would be a sanguineous stasis, or a hyperæmia, or a thrombosis, or an embolism. In other words, the process would be a simple digestion of the stomach by itself, or what may be termed local autophagia. Acting on these premises, Dr. Debove has adopted the following treatment in simple ulcer of the stomach. Having learned by experience that the introduction of large quantities of fluid, such as milk with or without lime-water or Vichy water, which up till now constituted almost the only remedy in the treatment of this affection, was often attended by the inconvenience of producing dilatation of the stomach of a more or less permanent character, Dr. Debove thought the enormous quantity of milk (5 or 6 litres) which the patient was obliged to absorb daily, might be considerably reduced in substituting some kind of liquid food, rich in nitrogenous substances. Starting on this principle, the beau ideal of Dr. Debove in order to obtain complete cure of simple ulcer of the stomach, would be to suppress for a time the secretion of the gastric juice, or rather to neutralize it by the action of alkaline substances, and thus render it inert. The following is his mode of procedure: During the first few days, he washes out the stomach so as to remove from it the acid and mucous secretions it may contain. He considers this operation absolutely inoffensive, so long as it is performed with a soft sound, so as to avoid perforation in case of the end of the sound coming in contact with the ulcer. He then administers three times a day a mixture composed of 25 grammes of meat powder diluted in milk, to which is added 10 grammes of bicarbonate of soda. This is introduced each time through the sound, on account of its disagreeable taste. Dr. Debove has never observed any bad effects from the large quantity of the soda, 30 grammes (nearly an ounce), daily, or, if there be any intolerance, the dose may be reduced and combined with calcined magnesia.

One of the principal advantages of this mode of treatment is to avoid dilatation of the stomach so apt to be produced by the ingestion of large quantities of fluid, taking into consideration the altered condition of the parietes of the stomach. Moreover, it is difficult to get patients to submit to a milk diet exclusively, which they are to take in small and frequent doses, hence the utility of an aliment more substantial and less bulky, which at the same time should be of easy digestion. This treatment, according to Dr. Debove, should not prevent the employment of other remedies as are usually adopted in cases of hæmatemesis, such as ice, tincture of iodine, the perchloride of iron, etc.

I have given the above description of Dr. Debove's treatment of simple ulcer of the stomach, but must leave it to your readers to judge of its advisability or practicability in such cases.

The epidemic of cholera which has been raging in Toulon for the last fortnight is the all-absorbing topic of the day, but the doctors are at variance as to whether it is the true Asiatic or sporadic cholera. At first the opinion was divided among the medical men at Toulon, but as the malady progressed they found reason to alter their opinion, and now consider that they have to do with the true Asiatic cholera or cholera morbus, which, however, is much less malignant than preceding epidemics. Drs. Brouardel and Proust, members of the Council of Hygiene in Paris, were despatched to Toulon to investigate the real character of the disease. On their arrival there they were inclined to look upon the disease as of a sporadic type, but soon after they too found it necessary to alter their opinion, and have pronounced it to be the Asiatic cholera. Both these gentlemen have since returned to Paris and read their report before the Council of Hygiene and at the Academy of Medicine in which they expressed themselves to the same effect. Dr. Fauvel, however, who was referred to as a high authority on the subject, persists in the opinion he has all along held, that the epidemic at Toulon is none other than sporadic cholera. Unfortunately for Dr. Fauvel, he has great odds against him, and however high he may stand in the profession, particularly as regards the subject of cholera, his opinion in the present case is considered of little value, as he has not visited any of the patients stricken with the disease. A discussion has been broached at the Academies of Medicine and Sciences on the subject, which promises to be very interesting, and we shall see whether Dr. Fauvel or his adversaries are in the right. Meanwhile the disease is dying out, and it is to be hoped we shall soon hear the last of it. The disease seems limited to Toulon and its suburbs, although a few cases have occurred at Marseilles. There is nevertheless a great panic, and the inhabitants from those quarters are daily flying away in all directions to escape contagion.

Dr. Bishop, an English physician who had been for many years in practice in Paris, died suddenly on the 23rd June, it is supposed from disease of the heart.

Dr. Moreau, better known under the designation of Moreau de Tours, to distinguish him from the other Moreaus in the profession, died at his residence in Paris on the 26th June, aged 81 years. He was an eminent alienist, and was pupil of the celebrated Esquirol. He took his degree in 1830. In 1840 he was nominated physician to the Bicetre asylum, and subsequently to the Salpêtrière, to which he had been attached for many years.

Dr. Koch, the eminent biologist of Berlin, has just passed through Paris for Toulon, on the same mission that took him to Egypt and to India, to study the pathogeny of cholera. Dr. Koch will there find his French co-workers, Drs. Strauss and Roux, in the same field, who belonged to the Pasteur mission to Egypt.

B.

NECROLOGY.

FRUITNIGHT, WM., New York City,—born of German parents in New York City, April 20, 1858. His education was obtained in the public schools of his native city, where he passed the various grades, graduating from the Grammar department, entered the College of the City of New York, where he was graduated A.B. in the class of 1878. He then entered upon the study of medicine with his brother, Dr. J. Henry Fruitnight, and Dr. C. A. Leale, subsequently with Dr. J. E. Winters and at Bellevue Medical College, where he received his M.D. in 1880. Subsequently he successfully passed a competitive examination for an appointment on the staff of Bellevue Hospital, where he served out his full term.

While in that service he never wavered in the fulfillment of any professional duty which he was called upon to face, and yet his convictions were always superior to formally expressed rules of action, wherefore he was often guided by the dictates of his own conscience, even though they might conflict with such prescribed regulations.

While there, when he had charge of the erysipelas pavilion he greatly overtaxed himself, like many of his predecessors he became a victim to septic infection, which most probably led to the ultimate cause of his early death. After leaving the hospital he became associated in practice with his brother, Dr. J. Henry Fruitnight, at 259 W. 54th st., and was rapidly securing a growing and extended practice, particularly in obstetrics and gynecology.

For a short time he was associated with Prof. W. G. Wylie in the N. Y. Polyclinic, in the department of Diseases of Women. He was for a short time associated with Prof. Louis Elsberg in the department of Laryngology at the same institution. He was associated with the St. Elizabeth Hospital in W. 31st st. He was a member of the Council of Bellevue Hospital Medical College, Alumni Associations, Northwestern Medical and Surgical Society, in whose meetings he always took active part, participating in all the scientific discussions; Empire City Council of Royal Arcanum No. 557, of which Council he was medical examiner. While he was studying medicine he taught in several of the evening schools of the city. His death was very sudden, occurring at his late residence on Sunday, July 20, 1884, at 11 o'clock A. M.

He had fulfilled arduous professional duties the day before. On the evening preceding his death he had a very difficult and complicated case of instrumental labor which caused him much anxiety and great expenditure of physical force. The cause of death was cerebral thrombosis sequel to pachymeningitis.

His obsequies were held at the residence of his brother on Tuesday evening, July 22, Rev. Dr. J. D. Wilson officiating. His remains were interred at Woodlawn Cemetery on the following day, in the presence of his family, a circle of friends, and a delegation from the Northwestern Medical and Surgical Society, and Empire City Council of Royal Arcanum.

E. C. H.

WALKER, CLEMENT ADAMS, M.D., born in Fryeburg, Maine, July, 1820, died in Boston, Mass., April 22, 1883. He graduated A. B. at Dartmouth College in 1842, with a class somewhat remarkable for the large number that have attained distinction. Delicate health compelled him to travel before taking his medical degree. He graduated M. D. from the medical department of Harvard University in 1850, and at once received an appointment in one of the public institutions in South Boston. Epidemics of cholera and ship fever having broken out soon after in Boston, he was among the first to volunteer his services and went to Deer island, in the harbor, and labored assiduously in the care of the sick. In 1851, he was appointed Superintendent of the Lunatic Asylum in South Boston, and, after thirty years' service resigned in January, 1881, on account of ill health. He was conspicuous for his kindness of heart and deep sympathy, making the insane feel that he was their personal friend, and in their treatment, besides the resources of the medicine, he had this requisite of success, that he was able to inspire them with the belief that they would get well. He was the first superintendent in this country to abandon the use of cells in the treatment of the insane, and was earnest in improving the old and in devising new methods for treating this class of patients. He was an unwearied worker, a kind friend, and a judicious adviser in hundreds of families where mental sickness brought sorrow. He was recognized as an able expert in mental diseases, and was of that judicial cast of mind that made his opinion valuable in matters relating to the complicated questions arising in his specialty. As a writer he was remarkable for terseness and perspicuity. Dr. Walker was one of the original members of the American Association of Superintendents of Hospitals for the insane, and for the last three years was its president, and from it was a delegate to the International Medical Congress, Philadelphia, 1876; a member of the New England Psychological Society of the South Boston medical club; of the Massachusetts Medical Society; and of the American Medical Association. He leaves a widow and three sons.

JOHN H. GILMAN, M.D.

Lowell, Mass., July 15, 1884.

MISCELLANEOUS.

THIRD INTERNATIONAL OTOLOGICAL CONGRESS.

We are in receipt of the programme of the Third International Congress which meets at Bâle, Monday, Sept. 1, 1884. The congress commences with a Rendezvous of Welcome, on Sunday, Aug. 31, and concludes with an excursion to the Lake of the Four Cantons, on Friday, Sept. 5, 1884. The work of the Congress is divided into three sections: I, Anatomy Normal and Pathological; II, Physiology, Methods of Examination; III, Pathology and Therapeutics.

We are surprised to find that among the communications promised, not a single name from America appears. In the department of Anatomy all of the

contributors are Germans; in Physiology, Paris and Naples are represented, whilst in Therapeutics contributors from various countries promise communications, practically America alone being silent.

OFFICIAL NOTICE.

ANNUAL DUES from members of the Association—*Five Dollars* per annum—are payable directly to the Treasurer. Such payment entitles them to receive the JOURNAL of the Association for one year.

SUBSCRIPTIONS TO THE JOURNAL from those who are not members should be forwarded to the office of publication, Chicago.

BACK VOLUMES OF THE TRANSACTIONS may be procured, at reduced rates, by addressing the Treasurer.

THE INDEX to the 33 Volumes of Transactions will be forwarded, postpaid, on receipt of *One Dollar* by the Treasurer.

According to a resolution passed May 9, 1884, at the Washington meeting, continuous payment of Annual Dues is required, to retain permanent membership.

RICHARD J. DUNGLISON, M.D.,

Treasurer.

Lock Box 1274, Philadelphia, Pa.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT UNITED STATES ARMY, FROM JULY 26, 1884, TO AUGUST 1, 1884.

Head, Jas. F., Colonel and Surgeon, ordered to Portsmouth, N. H., to meet the Greely party, and consult upon the proper course of treatment, with a view to the entire restoration to health of Lieut. Greely and the men of his command. (S. O. 177, Par. 14, A. G. O., July 30, 1884.)

Wright, Joseph P., Major and Surgeon, sick leave of absence extended three months on surgeon's certificate of disability. (By Par. 12, S. O. 176, A. G. O., July 29, 1884.)

McElderry, Henry, Captain and Assistant-Surgeon, so much of par. 12, S. O. 165, A. G. O., July 16, 1884, as assigned him to duty in Dept. of the East, is revoked, and he is ordered to report in person to the Surgeon-General of the army for duty in connection with World's Industrial and Cotton Centennial Exposition at New Orleans, La. (Par. 12, S. O. 173, A. G. O., July 25, 1884.)

Finley, J. A., Captain and Assistant-Surgeon, granted leave of absence for one month, with leave to apply for one month's extension, to take effect about September 1, 1884. (Par. 2, S. O. 91, Hdqrs. Dept. of Texas, July 22, 1884.)

Reed, Walter, Captain and Assistant-Surgeon, relieved from duty at Fort Sidney, Neb., and ordered for duty as post surgeon, Fort Robinson, Neb., relieving Assistant-Surgeon Henry McElderry, U. S. A. (Par. 2, S. O. 62, Hdqrs. Dept. of Platte, July 22, 1884.)

Benham, R. B., First Lieutenant and Assistant-Surgeon, assigned to duty at Fort Brown, Texas. (Par. 1, S. O. 90, Hdqrs. Dept. of Texas, July 19, 1884.)

Gandy, C. M., First Lieutenant and Assistant-Surgeon, granted leave of absence for one month, to commence between August 15 and 30, provided he furnish medical attendance at Fort Brady, Mich., during his absence. (Par. 5, S. O. 154, Hdqrs. Dept. of East, July 30, 1884.)

LIST OF OFFICIAL CHANGES IN THE MEDICAL CORPS OF THE NAVY, FOR THE WEEK ENDING JULY 26, 1884.

P. A. Surgeon G. E. H. Harmon, ordered to temporary duty at Norfolk Navy Yard.

OFFICERS OF
THE AMERICAN MEDICAL ASSOCIATION
 AND OF ITS SEVERAL SECTIONS, 1884-5.

PRESIDENT.

H. F. CAMPBELL, of Augusta, Georgia.

FIRST VICE-PRESIDENT.

J. S. Lynch, of Maryland.

THIRD VICE-PRESIDENT.

J. W. Parsons, of New Hampshire.

PERMANENT SECRETARY.

Wm. B. Atkinson, 1400 Pine St., Philadelphia.

SECOND VICE-PRESIDENT.

S. D. Mercer, of Nebraska.

FOURTH VICE-PRESIDENT.

H. C. Ghent, of Texas.

TREASURER.

R. J. Dunglison, Lock Box 1274, P. O. Philadelphia.

LIBRARIAN.

C. H. A. Kleinschmidt, Washington, D. C.

Place of meeting, 1885, New Orleans, La.; Time of holding meeting, last Tuesday in April.

COMMITTEE OF ARRANGEMENTS.

Samuel D. Logan, Chairman; S. E. Chaillè, E. S. Lewis, Joseph T. Scott, W. G. Austin, W. H. Watkins, J. P. Davidson, J. A. G. Fisher, Geo. W. Lewis, B. A. Pope, W. C. Wilson, M. Schuppert, Geo. J. Friedrichs, F. Loeber, D. Jamison, G. K. Pratt, L. F. Salomon, J. H. Bemiss, Geo. Lawrason, C. U. Gaudet, Sam'l M. Bemiss, C. J. Bickham, Chas. Turpin, Jno. Carter, A. W. DeRoaldes, S. S. Herrick, W. S. Mitchell, E. T. Shepard, E. Souchon, T. D. Layton, T. S. Dabney, S. R. Olliphant, Edward Harrison, A. B. Miles, Joseph Holt, P. B. McCutcheon, F. H. Parham, G. B. Underhill, Stanhope Jones, E. Chassaignac, J. Dell'Orto.

ASSISTANT SECRETARY.

W. H. Watkins, New Orleans, Louisiana.

BOARD OF TRUSTEES FOR JOURNALIZING THE TRANSACTIONS.

J. M. Toner, Washington, D. C., President;
 E. M. Moore, Rochester, N. Y.; Leartus Connor, Detroit, Mich.;
 J. H. Packard, Philadelphia;
 H. F. Campbell, Augusta, Ga.; A. Garcelon, Lewiston, Me.;
 P. O. Hooper, Little Rock, Ark.;
 L. S. McMurtry, Danville, Ky.; J. H. Hollister, Chicago, Ill., Secretary.

ORIGINAL ARTICLES.

THE TREATMENT OF HYDROPHOBIA, HISTORICALLY AND PRACTICALLY CONSIDERED.¹

BY CHARLES W. DULLES, M.D., OF PHILADELPHIA.

Fellow of the College of Physicians, and of the Academy of Surgery of Philadelphia.

The history of medicine can be traced back, more or less obscurely, to a period about 1200 years before the Christian era to whatever real or fabled healer may have been the foundation of the myth of Aesculapius, yet Aristotle, who lived from 384 to 322 B. C., is the first writer, whose works are extant, by whom we have distinct mention of the subject of hydrophobia. His reference to it has given rise to much discussion, because it does not accord with what is commonly believed about it, but there can be no doubt that he spoke of what is now known by this name. His expression is: "Dogs are subject to three diseases. These are called lyssa, cynanche and podagra. Of these lyssa causes mania, and whatever is bitten (*δταν ζσηη*) all those bitten go mad except man. (*λυττωσιν ἅπαντα τὰ δηχθέντα πλην ἀνθρώπου*)."² This disease seizes on dogs and whatever is bitten by a mad creature except man."

But we have also references to the sayings of earlier physicians about hydrophobia in the works of those who followed them. Thus we learn from Pliny,³ that Epicharmus, who is supposed to have died about 450 B. C., not only was familiar with the disorder, but also praised the use of the wild cabbage in its treatment. Following him we find Democritus, who was born about the time that Epicharmus died, speaking of it as an inflammation of the nerves.⁴ Eudemus, who lived in the third century B. C., is quoted by Dioscorides⁵ as declaring that a certain one had escaped the disorder; while Themison, who lived from 63 B. C., to 25 A. D., is said to have contracted the disorder while attending a friend, and to have escaped only after great suffering.⁶

However, the first account of hydrophobia in man which corresponds to the ideas of modern times is that given by Celsus, who speaks briefly but appreciatively of its horrors, calling it "miserimum genus morbi," and gives some excellent advice in regard to its treatment. He advised cupping the wound, cauterizing it—if it be not in a nervous or muscular part—and the use of emollient dressings. If the actual cautery cannot be applied, he says, "blood-letting is not unsuitable." When the symptom of a dread of water was fully developed, he declared the only remedy was to cast the unsuspecting patient into a pond, where, if he could not swim, he was now to be allowed to sink, and thus compelled to drink and again lifted up; while, if he could swim, he was to be pushed under again and again, until, even against his will, he was filled with water. For the shock which might result, he advised placing the patient afterward in a bath of warm oil.

This heroic method is said by Dr. Arnold⁷ not to have been original with Celsus, but copied from some of the older physicians—an assertion which seems reasonable in view of certain expressions of Cælius Aurelianus.

Not long after the time of Celsus, Pliny the Elder (b. 23 A. D.—d. 79 A. D.) published his famous Natural History, already referred to, in which he seems to have collated, with the utmost impartiality, all the reasonable and unreasonable ideas of his time in regard to a great variety of subjects. Among these, those about hydrophobia are not the least interesting, nor the most absurd. To the wound made by the bite of a mad dog, he suggests the application of raw veal. Some, he says, prefer (as a preventive of the hydrophobia) a he-goat's liver, or a she-goat's dung, with wine, or the dung of the badger, cuckoo and swallow, boiled and taken in drink. (Book xxviii, 43.) The ashes of river-crabs, he says, are good when the symptoms of the disorder appear. (Book xxxii, 19.) He praises, also, the ashes of the tail of a shrew-mouse, if the animal has survived and been set at liberty; a clod from a swallow's nest, applied with vinegar; the young of a swallow reduced to ashes; or the skin or old slough of a serpent that has

¹For bibliography of the subject, see paper on "The Disorders Mistaken for Hydrophobia" in Transactions of the Medical Society of the State of Pennsylvania, for 1884.

⁶Dioscorides, loc. cit.

As the passage referred to is sometimes misunderstood, I will give it here in full. "Sed unicum tamen remedium est, nec opinantem in piscinam non antè ei prouisam projicere, et si natandi scientiam non habet, modò mersum bibere pati, modò attollere: si habet, interdum deprimere, ut inuitus quoque aqua satietur. Sic enim simul sitis, aquæ metus tollitur." Celsus, Aurel. Corn. De Arte Medica libri octo Basilæ, 1552. Lib. V. Cap. XXVII.

⁷Arnold, Thomas, M.D. A Case of Hydrophobia. 8vo., pp. 245. London, 1793. P. 193.

been cast in the spring, beaten up with a male crab in wine. There is, he says, beneath the tongue of a mad dog a certain slimy spittle, which, taken in drink, is a preventive of hydrophobia; but much the most useful plan is to take the liver of the dog that has inflicted the injury, and eat it raw, if possible, and if not, cooked, and taken with the food, as a remedy for this disease. As to the popular idea of the nature of hydrophobia at that time we may gather something from the statement that "So virulent is the poison of the mad dog, that its very urine even, if trod upon, is injurious, more particularly if the person has any ulcerous sores about him." (Book xxix, chap. 32.)

Scribonius Largus, who flourished at about the same time as Pliny, cites a number of antidotes then in use.[†]

In the first century of the Christian era flourished also Dioscorides, who treats very fully of the effects of venomous bites and of mad dogs. He recommends for the bites of the latter the methods common to them and the former, and follows these with the administration of the ashes of river-crabs, burnt with a fire made of the twigs of white clematis, together with powdered gentian root. The most effectual remedy, he says, is hellebore; but even this will not avail after the symptoms of hydrophobia are fully developed.¹

The next writer who attracts the attention of the inquirer is Galen, who lived from 131–200 A. D. His recommendations are scattered through his extensive writings. There is little original in them. He specifies, after the teaching of his preceptor Aescrion, that the ashes of river-crabs, intended as a preventive of the hydrophobia, should be prepared by burning on a copper plate, in summer, after the rising of the dog-star, when the sun is in Leo.² Contrary to what one might suppose from some of the histories of hydrophobia, Galen was sceptical as to the advantage of eating the liver of the mad dog. He says he has seen some who, after doing this, had got well; but, he distinctly states that they had also used other means considered useful in such cases, and that he had also seen others trusting in the liver of the dog alone, who had lost their lives.³

In the next century (about 230 A. D.) lived Cælius Aurelianus, who is one of the most interesting characters in the history of hydrophobia. He is the first author, whose works are extant, to give a systematic account of this disorder. But he treats of it so fully that we are able to judge pretty well just what was the general state of information in regard to it up to his time. He discusses the causes, nature, symptoms, simulations, lesions, and treatment of hydrophobia in an orderly and intelligent manner, although he was not free from some of the current errors of his time, and wrote most atrocious Latin. In speaking of treatment, he recommends bleeding, to subdue fever, if any be present, and, if not, to subdue the

fear. He advises that when this is done the patient be made to turn away his face, and that the blood be caught in the hand, in order that its flow may not agitate the patient. He condemns in a most intelligent way the follies and superstitions which many of his predecessors had taught.¹

Aetius, who lived about 543 A. D., advised the administration of oxalis, and speaks of the eating of the liver of the cormorant—the virtue of which, he suggests, may depend upon the fact that patients must go to sea to get it. He also mentions the flesh of the sea-horse, the blood of its young, which creates a great thirst for water, taken internally. He also speaks of the skin of the bear, seal or hyena, applied to the skin as an amulet, and the skin of the hyena reduced to ashes and swallowed.²

Paul, of Ægina, who lived either at that time, or in the century following, speaks of the treatment of hydrophobia by the administration of the herb alysson, the liver of the mad-dog, the blood of a parturient, garlic, and onions. He concludes his chapter on this subject with the statement that the most effective treatment is helleborism.³

Of Rhazes (860–940 A. D.), Avicenna (980–1036 A. D.), Albertus Magnus (1193–1280 A. D.), Cardan (1501–1576 A. D.), Matthiolus (1501–1577 A. D.), though their names are associated with the history of hydrophobia, there is little worth mentioning when speaking of its treatment.

Ambroise Paré (1509–1590 A. D.), who entertained many of the erroneous notions of his time in regard to the nature and symptoms of hydrophobia, both in dogs and men, advised the use of antimony, with cathartics and sudorifics, good eating, moderate drinking, and the avoidance of sleep. For the treatment of the wound he followed the lead of Aetius in recommending the oxalis to be bruised and applied, and a decoction of it to be taken internally. He also advised the use of mustard dissolved in urine or vinegar, made into a lotion to be rubbed in and laid upon the wound on a double cloth; and finally, he says, all acrid, pungent and strongly drawing substances are useful.⁴

Palmarius (1520–1588 A. D.), published a receipt for a powder, which he said he had received from Sylvanus Count de Pyrou, composed of a number of vegetable substances, and which was in use so late as the middle of this century. (Lipscomb⁵ and Bouchardat.⁶) According to Sauvages he first suggested the use of mercurial frictions, in 1578.⁷

Schenckius (1530-1598 A. D.), Platerus (1536-1614 A. D.), Fabricius Hildanus (1560-1614 A. D.), and Zacutus Lusitanus (1575-1642 A. D.), though also identified in other respects with the history of hydrophobia, have not contributed anything of special interest to its therapeutics.

Van Helmont (1577-1644 A. D.), recommended the cold bath, or rather what had come to take the place of this recommendation of Celsus, namely, ducking in the sea. He tells an interesting story of a cure he witnessed. "There is," he says, "a Fortress on the sea-coast, about four leagues from Ghent, called Sluce. There I saw a ship passing by, and in it an old man, naked, bound and weights fastened to his feet. Under his arms they had tied a rope, the other end of which was fixed to the yard-arm of the vessel. I asked the meaning of this spectacle, and was answered by one of the sailors that the old man had got the hydrophobia, having, some time ago, been bit by a mad dog. Why, I asked, is he brought to the sea? whether they meant to drown him? No, no, (said the sailor), he will soon be cured; such is the blessing of God upon the sea that it will instantly cure this kind of madness. At my request they took me on board. We had scarce sailed a mile when the sailors, by pulling out a plug in the bottom of the ship, let in the water till she sunk almost to the edge of the gunwale. This sea-water they collected for the purpose of making salt. The plug being now readapted, two men hauled down the opposite end of the yard, and thus hoisted the old man into the air. They then let him drop into the sea, and he remained under water *ad spatium Miserere*. They repeated this operation twice more, keeping him each time under water *ad spatium salutationis Angelicæ*. They then laid him on his back across a barrel, and covered him with a watch-coat. I concluded he was dead; but the sailors ridiculed my apprehensions. Being now released from his bonds he discharged all the water which he had inspired, and presently revived. He was a cooper from Ghent, and being cured of hydrophobia, continued perfectly well."¹

In 1625 Aromatarius, a physician of Italy, published a most interesting monograph on hydrophobia, which he held to be a contagious angina. With this in view, he recommended the practice of laryngotomy.² The first proposal of this method for the treatment of hydrophobia he attributes to Asclepiades, on the authority of Cælius Aurelianus, who, he says mentions and condemns it. In this, however, Aromatarius was mistaken, for both of these authors spoke of laryngotomy only in connection with indubitable cynanche,³ and the credit of its suggestion for the treatment of what is taken to be hydrophobia is entirely due to Aromatarius, and not at all to these ancient men.

In 1656 Salius Diversus published a book on pestilential fever, in which he treats of the hydrophobia, in a way that is intelligent to a degree quite remark-

able for his times. He had little faith in the modes of treatment proposed, and thought the cases of reported cure must have been of incipient, and not fully developed hydrophobia.¹

Bœrhaave (1668-1738), though saying that little confidence could be placed in preventive treatment, advised free and deep scarification of the wound made by a mad dog, followed by cupping and the actual cautery. After this the wound was to be kept open and suppurating. After infection of the system he recommended casting in a river or the sea, with great display, so as to make a strong mental impression. At the outbreak of the disorder he advised bleeding "*ad deliquum*," and to bind the eyes and cast into a cold pond.²

Ravelly,³ in 1696, recommended the use of emetics, diaphoretics, diuretics and purgatives. He says that everyone knows that the best plan is to plunge the patient several times into the sea. He first recommended the use of mercury internally, and praises the virtues of camphor even still more highly. His most remarkable recommendation, I have been surprised not to see in any of the monographs on hydrophobia which I have read. This is the transfusion of the arterial blood of some animal into the veins of the sufferer. For this purpose he says the blood of the he-goat is the best, and explains why.

In 1698 Mr. George Dampier communicated to Dr. (afterwards Sir) Hans Sloane—who then gave it to the public⁴—the composition of a secret remedy, the *Lichen cinereus terrestris*, or grey ground-wort, which became afterwards a part of the *Pulvis antilyssus*, long famous and much esteemed in England.

This remedy was subsequently introduced to the general public by Sir Hans Sloane in a brief pamphlet which treats of disorders of the eyes, and to which this is a mere addendum.⁵

This pamphlet was in 1767 translated into French, and its value much enhanced by M. Cantwel.⁶

About this time (1700) Sir Theodore Mayern proposed to the British public the following interesting procedure, which was calculated not only to serve as a test of the state of a dog suspected to be mad, but also as a curative method, in case it was: "Pluck the *Feathers* from the *Breech* of an old *Cock*, and apply it bare to the *Bite*, and do this upon each of the *Wounds*. If the *Dog* were *Mad*, the *Cock* will *Swell* and *Die*, and the *Person Bitten* will do well; but if the *Cock Dies* not, the *Dog* was not *Mad*. If

the *Wounds* be very small, it is requisite to open them with a Lancet."¹

We now come to the time of the great Dr. Mead, (1673-1754 A. D.) who in his various writings, has had a great deal to say about hydrophobia. His notions bear in part the impress of the opinions of his times, and more conspicuously the marks of his own original and fanciful notions in regard to pathology, and the influence of the heavenly bodies on the human frame.² In regard to the treatment of hydrophobia, he is most noted for having devised the *pulvis antilyssus*, which was at first composed of equal parts of the lichen cinereus terrestris and piper niger, but afterwards, as Dr. Mead says, on account of its too great heat in this shape, of only half as much of the pepper. This powder was in 1721 inserted in the London Pharmacopœia, and for many years not only held the confidence of the English medical men, but was also much used in foreign lands. Mead says he had seen the liver of the dog eaten in his time, but without success. In his first medical publication he stated that "The greatest and surest Cure of all, is frequent Submerging or Ducking the Patient in Water."³ After his composition of the *pulvis antilyssus* he spoke of this as a "sure cure."⁴

About this time Desault⁵ (1732) published his interesting book on the venereal and other diseases, in which he recommends, as a specific, inunctions of an ointment he calls "Neapolitan," composed of equal parts of human fat, hog's lard and mercury. As a concession to the prejudices of his time he permitted also dipping in the sea, the wearing of amulets, religious rites and various diversions. Desault's practice was founded upon the theory that hydrophobia was communicated by the transfer and breeding of certain "insects or little worms," herein being analogous, he said, to the "Venereal Distemper."

In England, Dr. James (1703-1776) next attracts our attention in connection with the treatment of hydrophobia. This is the Dr. James whose fever powder was so long in use all over the world. He is said to have been—and, so far as I can learn, was—the first to suggest in England the use of mercurials for hydrophobia. This suggestion, though it had been made nearly 200 years before by Palmarius, as we have seen, seems to have appeared new to Dr. James, and was the outcome of some investigations in regard to the effect of mercury on dogs, which he reported to the Philosophical Society,⁶ in 1735. His suggestion was to give the Turpeth mineral internally and to use inunctions, in the manner which had shortly before been proposed by Desault. He had some faith in

the *pulvis antilyssus*, and also in what was known as the Tonquin medicine, a remedy brought from Tonquin by Sir George Cobb, which was composed of musk with native and factitious cinnabar.¹

About this time also appeared the famous composition of one Hill, an apothecary at Ormskirk, which has since been known as the Ormskirk remedy. This was made of chalk, Armenian bole, alum, elecampane root and oil of anise. This too had a great reputation in its day.

At this time too the use of belladonna was begun in Germany.²

As late as 1753, I find that Andree had a case where he found his patient had been made to eat the cooked liver of the dog which had bitten him. Andree himself approved of Desault's method, and used it.³

Dr. Robert Whytt (1714-1766 A. D.) recommended the use of opium in large doses, upon the theory that "the hydrophobia is only a violent convulsion of the gullet and stomach, etc., arising from the disagreeable sensation excited by any liquid touching the fauces, or by the effort the patient makes to swallow them."⁴

This recommendation of Whytt has found its most heroic following in the practice of Babington, who gave a patient within twelve hours 180 grains of opium, besides giving him a hot bath, blistering and bleeding him, and using an inunction of strong mercurial ointment. The patient—which is hardly remarkable—died in 15 hours.⁵

In 1784, one of the most astonishing suggestions in regard to the treatment of hydrophobia was made by M. de Mattheis, Surgeon in the army of the King of Naples. Seeing one day a dog supposed to be mad, and which had a convulsion when water was offered to it, he applied to its throat a viper, and excited the latter to bite. At once, he says, the dog's head swelled up, the hydrophobia ceased, and the animal recovered.⁶ Soon after, in 1788, Fabbroni reported a case⁷ where the same treatment, with the modification that there were two vipers employed, which were applied one to each leg, was used upon a man. The patient seemed to be relieved for a moment, but he died in half an hour.

In 1789, Dr. Percival suggested the application of fresh gastric juice, or the saliva of a healthy young person, obtained by chewing rennet, to the bite of a mad dog, after the wound had been thoroughly washed in the manner recommended by Dr. Haygarth. He also gave an interesting account taken

from Abbé Grosier's "Description of the Chinese," of a species of porous stone, used in "Tang-King," and called a "Serpent-stone." This stone was applied to the wounds of serpents and mad dogs, whereupon it adhered, drew to itself the virus, dropped off, and the patient was saved. This stone, after washing in lime water and drying, could be used over and over again. This is the earliest allusion to the so-called "mad-stone," which I have found.

The next reference to the "mad-stone" which I have found is contained in an unpublished letter to Dr. Rush from a Mr. Samuel Davis of Petersburg, Virginia, dated Oct. 2, 1801. In this the writer tells of his endeavors to avert the hydrophobia from a son who had been bitten by a suspected dog. The boy, after some domestic applications, was, by the advice of a physician, cauterized and blistered almost down to the bone of his arm. He was then almost wild, and was taken to a person reputed to have a "mad-stone." With the performance of this stone the father was not satisfied, because, contrary to his expectation, and the popular belief about such stones, he could see no evidence of the poison boiling out of it after its removal. He therefore took his son to a second person owning a "mad-stone." The application of this he graphically describes, and his seeing, after it had remained on for periods of twelve hours and was taken off and put into water, some bubbles arise from one corner of it, which the owner of the stone told him was the poison coming out. An investigation of the history of this stone—for which the owner said he had refused an offer of 300 guineas—revealed the fact that it had been given by a stranger who had been hospitably cared for when sick. It was wrapped in a piece of paper dated Charleston, South Carolina, 1740, and having printed on it the following: "Francis Torres a native of France is in possession of a chymical preparation, called a Chinese snake stone, which will extract the poison of the bite of snakes, spiders, and of a mad dog, and will cure cancers, which are sold at half a guinea for the small and a guinea for the large ones."*

We have now come to the beginning of the present century, a time when the prevailing method of treating hydrophobia was with bleeding and mercury. The most instructive writer on the subject of hydrophobia about this time was Mease, who, in 1792, published an inaugural dissertation, on taking the degree of Doctor of Medicine in the University of Pennsylvania, which is one of the most valuable publications on the subject which have appeared in any time. His studies, then¹ and afterward,² led him to dissent from the view of Dr. Rush that hydrophobia was a malig-

nant fever, and to oppose blood-letting; while he thought as well of mercurials as of anything.

Dr. Rush, on the other hand, at first believed that hydrophobia was a malignant fever—an opinion which, though incorrect, was not novel, for, long before, Eustachius Rudius had called it "*a putrida maligna humiditate caput petente morbum*."¹ Dr. Rush, thinking as he did of the nature of the disorder recommended free blood-letting, saying: "The loss of 100-200 ounces of blood will probably be necessary in most cases to effect a cure."² In 1811 I find he made the following endorsement on the back of a letter from Dr. A. C. Peyton, of Virginia³ (who wrote in great anxiety because he had had his hand scratched by the teeth of a mad steer, to which he was administering medicine):

"May 31, answered his questions—

"1. No animals communicate the hydrophobia but dogs, cats and foxes.

"2. Cutting out the wounded part at any time before the disease comes on, prevents it.

"3. The wound should be kept open 4 or 6 weeks.

"4. There is no medicine taken internally that prevents the disease."

Later still he came to the opinion that hydrophobia was essentially a spasmodic disorder of the larynx, and recommended laryngotomy.⁴

This last proposal of Dr. Rush was a modification of that made by his friend Dr. Physick, who, after observing a single case, concluded that the trouble was due to a spasm of the glottis, and, in 1802, advocated the performance of tracheotomy.⁵ We have here another interesting illustration of how history is unwittingly repeated; for, as we have seen, this operation had been recommended for employment in hydrophobia by Aromatarius, about two hundred years before, while—though in this he was mistaken—he had attributed the first suggestion of it to Asclepiades, before the Christian era.

About the beginning of this century galvanism, which had nearly 40 years before been used in the treatment of tetanus,⁶ was used by Rossi with entire success in a case he considered to be one of hydrophobia. In the very dramatic report of a case which was given by Vassali-Eandi to the Academy of Sciences of Turin, it is stated that Rossi, having extemporized a galvanic battery, made his patient stand barefooted on sheets of coarse, wet paper connected with one pole, and thrust a conductor, connected with the other, into his mouth *whenever he opened it to bite!* In this manner shocks were repeated until the patient was unable to stand, and was covered with beads of sweat. The next day he came back and reported himself cured, and, notwithstanding the solicitations of the

enthusiastic operator, declined to undergo a repetition of the treatment.¹

Delabere Blaine, who is regarded as the pioneer of intelligent veterinary medicine in England, and who corrected a number of popular errors about rabies in dogs which had prevailed up to this time, believed he had been saved from hydrophobia by a nostrum, and declared that excision was as effectual at the end of the first, second or third week as at the first.²

Youatt, the veterinarian, who built his ideas, to a considerable extent, on those of Blaine, had a most extravagant faith in the cauterization of the bites of mad dogs with the nitrate of silver, and advised its use even after the constitution has been affected.³

Dr. Parry, who was one of the most intelligent writers on the subject of hydrophobia, and whose interest in the subject extended over a period of nearly 40 years, despaired of curing the disorder when once it was fairly developed, but advised even late excision of the cicatrix and its immediate surrounding tissue as a preventive measure.⁴

In 1820, Marochetti, an Italian surgeon, announced that he had learned, in 1813, from a Cossack peasant in the Ukraine, that there were, in cases of impending hydrophobia, certain vesicles beneath the tongue, (which are known in history as "lyssi") the excision of which would prevent the outbreak of the disorder.⁵

This so-called discovery has been robbed of its novelty by an excellent report of Auzias-Turenne to the French Academie de Médecine,⁶ in which it is shown that the lyssi were explicitly indicated by Pliny, Demetrius, Pepagomenus and Fracastor; that they were known by tradition in Greece, Turkey, Spain, and Galicia.

The practical value of the theory of the lyssi has long been known to be *nil*, although even such recent writers as Trousseau⁷ and Doléris⁸ have given them credit, and the latter has accepted a story of the inoculation of the contents of them, so as to produce an artificial rabies in horses.

About this time Urban propounded the theory that the virus of hydrophobia is at first deposited in the immediate neighborhood of the wound, and it is followed by the development of certain vesicles which contain the virus and have inoculable contents, like the "lyssi." He recommended bathing the wound with acidulated, warm milk, applying cups, and then salt solutions. The vesicles were to be carefully looked for, and, if they appeared, they were to be opened and treated like the original wound.⁹ He en-

forced these recommendations by citing a number of cases where he had, according to his own statement, saved his patients' lives in this way.

In 1821, Magendie proposed and experimented on a dog with intravenous injections of warm water. Afterward he treated a man who had symptoms like those of hydrophobia after strong emotional excitement, with an intravenous injection of two pounds of warm water, he having been well bled several times before. The result was a temporary calm, followed in two days by hæmorrhage from the bowel, then by abscess of the leg, and death on the ninth day. Magendie's theory was to produce an artificial aqueous plethora, to enfeeble the functions, and especially the nervous system. The dog he experimented on died as well as the man.¹

This method was also tried successfully by Gaspard, in 1824.²

In 1831 Trousseau, at the recommendation of Magendie, gave to a patient of Recamier's, whose *interne* he was at the hospital at that time, what was supposed to be 36 drops of officinal hydrocyanic acid. The patient, a young man, fell at once, as if dead. It was then learned that the drug clerk had made a mistake, and sent Prussic acid instead of what was ordered. Trousseau thought, of course, that the patient was killed; but, strange to say, his symptoms were somewhat relieved, and he was given several smaller doses afterward. He died, however, within twenty-four hours.³

Let us now advance our review of former methods of treatment of hydrophobia, at the cost of omitting some that are curious, but none that have proved efficient, to the year 1852, when Bouchardat⁴ made a report to the French Academy of Medicine, at the request of the government, upon a large number of proposals sent in just before that time for the cure of hydrophobia. This report contains, among other curiosities, the composition of a famous cabalistic omelette, made up of the lower shells of male oysters, powdered, with eggs and oil. One of the proposals—which came from a "Chocolatier" of Thernes—was to inoculate the patient with the virus of small-pox. The proposer claimed that he had treated and cured more than twenty persons in this way. A certain M. Vau proposed that the patient should be choked and thrown on a very hot brazier, so as to be well burned. After this he was to be cast into the water, "to extinguish him, and to counter-balance the two electro-magnetic currents." The "Countess of Saparta" wrote that she had observed that when she squeezed the anus of her dogs between her thumb and finger, she pressed out a yellowish fluid. This she did every fifteen days, and her dogs had not gone mad. She asked, therefore, if the virus

of rabies were not in this, and suggested inoculations with it as a preventive.

Bergeron, so recently as 1862, reported a case of a child, 12½ years old, to whom he gave hypodermic doses of $\frac{1}{10}$ grain of atropia.¹

In 1863 M. de Moerenhaut, formerly Consul at Los Angeles, claimed that hydrophobia originates in pole-cats, and does not exist where these are not found. From the same source where he gathered this information he learned that the application to the wound of chewed confitura leaves, and swallowing the expressed juice, was a preventive of hydrophobia.²

To conclude this purely historical part of our study, I will merely mention the use of the *Xanthium spinosum*, which was proposed as a remedy by G. R. Zymala,³ or Grzymala,⁴ in Russia, about 1866. It was tried experimentally at Alfort, and found unreliable, notwithstanding the extravagant claims of its proposer. Doléris says that this drug was said to have cured 100 cases in Podalie and the south of France in 1876—a statement which he utterly rejects.

That this sketch of the remedies which have been in use in the past is but a sketch, will be appreciated by any one who looks over the list of remedies given by a single author, Saint-Martin,⁵ which includes 39 from the mineral kingdom, 213 from the vegetable, 86 from the animal, and 9 compound nostrums. I have not mentioned a large number of charms, rites, and mummeries; to make a complete list of them would make up a volume and waste a life-time. But enough has been exhibited to show how vainly the previous generations have struggled with the strange problem presented by the current theories as to the nature of hydrophobia.

We may now turn to a consideration of the methods of treating hydrophobia which have been recommended in such recent times as to constitute practically the methods of our own day. The most important of these consist in the administration of morphia, chloral, curare, cannabis indica, hoang-nan or pilocarpine, by the mouth or rectum, or hypodermically, inhalations of chloroform, nitrite of amyl or oxygen, and the application of electricity. In discussing these, we must exchange the historical for the critical attitude, and endeavor to determine, as we go along, what claim each method has on the confidence of the world.

Morphia is the natural successor of opium, which, as we have seen, has been long in use. It is easy to understand how it might have been assumed *a priori* that opium, or its active principle, would be useful in the treatment of hydrophobia; but it is hard to understand why its invariable failure to save life should not long ago have led to its being discarded. And here we come upon one of the many paradoxes with which the history of this disorder is full, namely, that the remedies which have been most steadfastly praised

and commended, which have held their ground the longest, are the very ones which have oftenest failed. Opium is one of these deceivers. Bleeding was another. We have seen that Dr. Rush advised bleeding to the extent of from 100 to 200 ounces, and no one can claim that the method did not get a fair trial, for its advocates bled often enough and freely enough to satisfy the most exacting. As Dr. Pearson remarked in 1802: "In some of the unsuccessful cases, the quantity of blood drawn was astonishingly great."¹ And Desault cites a case from Clement where twenty pounds of blood were taken from a patient.² Yet, in the face of this, the advocates of bleeding urged it again and again, and charged its failure upon the timidity of those who employed it.

The same may be said of the use of mercury. Notwithstanding the fact that for two hundred years it has been tested and found wanting, it has been recommended from writer to writer until even so recent an author as Doléris, in 1881, gives it a sort of side glance of approval. And this is a remedy the use of which was founded upon an assumed similarity between the poison of syphilis and that of hydrophobia, and the belief, as John Douglas bluntly put it, that "that antidote, which most effectually expels the malignant and deadly poison conveyed by the sting in a harlot's tail, must also be the best antidote against the sting of the scorpion, the bite of the viper, rattle-snake, and all the serpents in the East or West Indies."³

I think that of morphia even a more severe condemnation may be formulated. I have studied the details of many cases where it was used, and I cannot recall a single one where it has seemed to have done any real good. But I can recall, from my reading and experience, many cases where I feel sure it has done a great deal of harm, where the opium or morphia has, in my judgment, been largely responsible for the delirious excitement, which has been kept in a flame of fury by the physical surroundings and management of the patient, until it and they have succeeded in parting the soul and body of the poor sufferer they were intended to relieve.

Chloral, I think, is open to the same objections as morphia, although I do not believe it as absolutely pernicious. I have failed to discover any evidence that it is of real value, and I think it is absolutely dangerous in the large doses often recommended. Some of the cases I have studied have left on my mind the impression of an accumulation of the doses given, followed by their absorption all at once, with the effect of sudden heart-failure and collapse.

The use of curare in the treatment of hydrophobia is said by Dolan⁴ to have been proposed first by Prof. Sewell early in this century. It was first used in 1861, at Milan, but was not successful. In the next year, I find Bergeron⁵ regretting that its scarcity may

prevent its general use as a remedy. Yet it is often thought that it was first used by Offenbergh, who, in 1875, published an inaugural dissertation containing an account of a case of supposed cure by its means.¹ In the next year Dr. B. A. Watson, of Jersey City, had a case which, though it lacked the symptoms of spasm of deglutition and inability to drink, he and Prof. Austin Flint concluded—the latter rather hesitatingly, indeed—to be a case of hydrophobia, or rabies canina. Apparently without being aware that curare had ever been used in this disorder, Dr. Watson proposed it, and with Dr. Flint's concurrence, administered it hypodermically, and the patient got well. This has been cited as a case of cure by curare, but this cannot be done unqualifiedly when it is borne in mind that the patient was treated for awhile with strychnia, and for the three most important days of his illness he received large quantities of brandy.²

A few other cases of supposed recovery after the use of curare have been reported; but I think they are not to be relied on as indicating that this drug has any curative action in hydrophobia. And there are many objections to curare. The drug is a compound of uncertain composition and unequal strength, and it is often impossible to obtain. In addition to this its effects are calculated to mask, but not to benefit the morbid state which constitutes the hydrophobic condition. Waterton hoped that it might at least produce a calm death; others have, I think, found that this is what it can do at most. Thus, in a case reported in the *Lancet*, Oct. 15, 1881, we find that, after an attempt to chloroform the patient, which had to be discontinued—to quote the exact words of the report:—"One-tenth of a grain of curare (Savory and Moore's gelatine disc) was administered hypodermically at 4:20 P. M. Patient died quietly at 4:30 P. M., asphyxiated."

Cases similar to this, though less striking and conclusive can be found scattered through the medical journals of the past ten or fifteen years, and they have led most students of the therapeutics of hydrophobia to the conclusion that curare is as worthless as any other of the many remedies which have from time to time attracted the attention and deceived the hopes of mankind.

The use of cannabis Indica was, so far as I know, first suggested by Mr. Cæsar Hawkins, in his "Contributions of Pathology and Surgery," vol. i, p. 74.³ In 1881 Mr. Ruxton, an India surgeon, reported⁴ a case of a boy, 5 or 6 years old, whom he supposed he had cured of hydrophobia by five minim doses of the tincture of this drug.

This remedy has one thing in its favor, and that is no small matter, namely, its mildness. The evidence is not sufficient to warrant any strong expression as to its value, but its usefulness in simple mania would seem to indicate that, if not used in toxic doses, it might prove serviceable in hydrophobia also.

The next remedy to which I call your attention is

also from the far East. This is the "Hoang-nan." Hoang-nan is a vegetable substance obtained from the *strychnos gaultheriana*, which was introduced to the French from Tonquin, about five years ago, by a M. E. C. Lesserteur,¹ who claimed, as is not uncommon with those who propose remedies for hydrophobia, that he had used it successfully in a large number of cases. He stated that he had given it in more than 100 cases bitten by rabid dogs, and in none has he known of the appearance of hydrophobia. This remedy has attracted but little attention, although it has been pretty well discussed in France and its effects in the hands of others has not been calculated to justify the hopes of its proposer. The virtue of the remedy—if it can be supposed to have any—depends upon the fact that the hoang-nan contains strychnine and brucine. A case which ended in recovery was reported by M. Barthélemy last year.²

But this remedy has entirely failed to gain a foothold even in France, where, as has been said, it was pretty well discussed about two years ago, and has been hardly noticed, and, I think, never used anywhere else, unless we believe the stories of its extensive employment in the East, of which I have seen no trustworthy evidence.

Within the last few years jaborandi, or its active principle, pilocarpine, has been highly vaunted for the treatment of hydrophobia, and a certain number of cases of supposed cure by its use have been reported. But they will not bear sifting. One of the most notorious of these was reported to the French Academy of Medicine, by M. Denis-Dumont, in 1882.³ This case was so circumstantially narrated, and seemed so conclusive, that it was cited by a large number of foreign journals as an actual cure of hydrophobia by the treatment employed. But unfortunately for the credit of the remedy, the case was referred by the Academy to a commission, consisting of Mm. Bouley, Bergéron and Leon LeFort. This commission, in an elaborate report, presented by M. Bouley, declared that it was not a case of hydrophobia at all.⁴ In addition to this negative opinion, there is, in the same volume, where the case is reported, a letter from a M. Victor Chatel,⁵ who was familiar with the history of the case, and there can be no doubt from what he says that the patient, being a hard drinker, was suffering only from the effects of alcohol and the rough handling of the people who first had charge of him, one of the proceedings of whom was to tie the man to a tree.

The conclusion which Germain-Sec⁶ and Dujardin-Beaumetz,⁷ came to, and which M. Barthélemy has stated in his paper on Hoang-nan,⁸ in regard to jaborandi and pilocarpine, is, I believe, the correct one.

namely, that they rather aggravate than ameliorate the disorder.

It is not worth while to more than refer to certain other remedies which have been used of late, but which have no claim upon the serious attention of the present day. Among these are valdivine, (the active principle of the *Picrolemma valdivia*), hyoscyamine, codeia, false angustura, pelletière, arsenic, arsenite of strychnia, the bromide of camphor, ammonium, calabar bean.

The remedies administered by inhalation are chloroform, nitrite of amyl and oxygen. Nitrous oxide gas has also been used.

The inhalation of chloroform was first proposed and used by Dr. Henry Hartshorne, of Philadelphia, in 1848. But it has not been found of any real merit. Doléris thinks it is absolutely injurious. It has seemed to me that its use, in conjunction with a hypodermic injection of morphia, in the manner known as a mixed narcosis, as proposed in 1877, by Nussbaum, might prove useful, even though neither of these remedies ought to be used alone.

The use of nitrite of amyl was first suggested by Dr. W. S. Forbes in a paper read before the College of Physicians of Philadelphia, April 7, 1875,¹ and was first employed by him in 1877.²

This method has been imitated in a few cases, but it has thus far shown no curative value whatever, and has not received the indorsement of any well-known writer on hydrophobia.

The inhalation of oxygen for the treatment of hydrophobia was first practiced by Drs. Schmidt and Zebeden, in Russia, in, or about, 1879. The patient was made to inhale three cubic feet of the gas, whereupon the paroxysms came to an end. The next day they recurred, and the inhalation was repeated, and continued for forty-five minutes. After this the patient recovered. The reference³ which I have in regard to this case leaves much to be desired on the score of completeness. But the hope that inhalation of oxygen might quiet the paroxysms of hydrophobia seems to get some support from the assertion of Dr. B. W. Richardson that oxygen has a distinct antispasmodic influence, though his inference, after seeing a case of tetanus treated in this way by Sir James Paget, that the profuse sweat in which the patient was bathed, indicated a special eliminative action upon the *materies morbi*,⁴ must be regarded as rather fanciful. As long ago as the year 1830, however, this matter of the possible utility of the inhalation of oxygen for the treatment of hydrophobia, was carefully considered by Dr. Murray, who came to the conclusion that no help was to be expected from it.⁵

Nor is the use of electricity, which has been recently reintroduced to the notice of the profession, so novel a thing as we might suppose. As we have

elsewhere seen, this was first used near the beginning of the century. But it has been resorted to again quite of late in France, and Doléris, writing in 1881, says it has been reported to have effected cures in five or six cases in Italy, and, while he admits that on more extended trial it has failed, yet he claims that recently reported cases indicate that it effects in a rapid and durable manner the diminution, if not the entire disappearance, of the paroxysms. Unfortunately, I can not find any confirmation of this hopeful statement. The last case I am aware of, which was treated in this way, was a patient of M. Germain Sée, who died, in spite of the use of pilocarpine, hoang-nan, and electricity to the region of the medulla oblongata.¹

We now come to the question, what is the method of treatment of hydrophobia which a careful study of the experience of the past, and a just appreciation of the disorder we are considering, indicate as most likely to be of benefit? To answer this question I will suppose one has been called to a case which is suspected to be one of hydrophobia, and describe the measures I think should be adopted under such circumstances. The first thing to be done is to bring some sort of order out of the confusion which is apt to reign before the doctor arrives. Well meaning, but hurtful, gaolers must be called off from the patient, the horrified and horrifying spectators must be dispersed, the patient must be placed in as quiet surroundings as possible, while the doctor strengthens those about by himself setting an example of steady composure. A tolerable degree of quiet having been secured, the next step must be to ascertain what is the real nature of the disorder with which the patient is afflicted. I have elsewhere shown* that there is a large variety of organic and functional diseases having no connection with the bite of a rabid animal, in which the symptoms of hydrophobia are presented. The physician should be familiar with all these and search for their presence with a most rigid examination; and only when all possibility of their presence has been excluded should the diagnosis be concluded upon as one of hydrophobia. If any one of these simulating disorders be found to be the cause of the symptoms, of course the treatment should be that which is proper to that particular disorder. Into the details of this we may not now go. One paper would not suffice to describe the treatment of so many diseases.

But, if the most painstaking and intelligent investigation leaves no alternative but to conclude that the disorder is indeed what is generally understood

¹ Bul. de l'Ac. de Méd., 1882, p. 713.

Since this paper was prepared M. Pasteur has announced that he has devised and practiced a method of preventive inoculations with an attenuated virus of rabies, so that he has thereby rendered certain dogs absolutely incapable of contracting the disease. As he has not tried his method on human beings, and does not dare to suggest that it shall be so tried, it might be thought that it does not concern us at present. But in view of the fact that this announcement was given in a sensational shape to the newspapers, and that it was accepted by many medical men, as well as the laity, as furnishing a reliable means of protection against death from hydrophobia, it may be worth while to put those who are not familiar with M. Pasteur's methods in general, and what he has and has not done in regard to the subject of hydrophobia in particular, on their guard against too hasty an acceptance of this announcement, and to protest against it, as founded upon false premises, arrived at by false reasoning and being a false conclusion.

by the term hydrophobia, then a plan of treatment must be adopted which corresponds with what is known in regard to the nature of this disorder. Such a plan includes certain general—we may say, moral—principles as well as a *modus medendi*. Indeed, I believe the former are of a greater importance in our present state of knowledge, than the latter. The first general principle to be observed in the management of a case of supposed hydrophobia is not to be misled by the real or apparent inability of the patient to drink; and joined with this should be an attempt to prevent the patient from being misled by it. The doctor should know that this symptom, in the very manner and form supposed to be peculiar to hydrophobia, may be absent in this and present in a number of other disorders. The patient should be also informed of this fact in every case. Further, both doctor and patient should get rid of the time-honored but utterly erroneous notion that the patient's life is endangered by this inability. And, since this is so, all attempts to induce a patient to drink are useless at the best and pernicious at the worst. As a means of aiding the diagnosis they are of no use to the physician, and they always do harm to the sufferer. If this sufferer be a little child, and force be used, as it too often has been, to compel the patient to drink, then the perniciousness of the practice rises to the point of absolute cruelty, and marks at once the ignorance and the hardness of the doctor.

Only less reprehensible than this are such tests as presenting a looking-glass to the patient, or blowing or sprinkling water on him, which ought to be forever banished from an enlightened medical practice.

Almost every writer on the subject of hydrophobia warns against the danger of making inquiry in the hearing of a patient, after a suspected bite. I think that one might even go farther than this, and say that inquiry after a bite of a mad creature may well be postponed altogether until after the death or recovery of the patient. The knowledge of such a bite is never necessary to the diagnosis, and the determination that no such a bite has occurred does not overthrow it. Such inquiries always do harm to the patient or his friends, and they never do any good to the doctor, at that time. He may therefore well exercise his patience, and restrain his curiosity until his patient is recovered or dead, when an exhaustive detecting of all the elements of the case may contribute to the advance of science without prejudice to the subject of the investigation.

But, while observing the precautions just mentioned, I think one may err in preserving too scrupulous a silence or insincerely repudiating the idea of hydrophobia. If this idea really has not entered the head of the patient, then it ought by no means to be suggested. But if it be already there, the subject must not be so studiously avoided—much less made the occasion of lying—as to betray to the patient the despair with which it fills the doctor. The latter need never deceive himself with the notion that he can thus hide the dreadful conviction which has taken possession of him. When matters have come to this pass, frankness and as much fearlessness as can be

summoned are best calculated to win the confidence of the sufferer.

On the other hand, while the doctor is avoiding the useless attempt to deceive his patient, by a too significant silence, as to the apparent character of the disorder, he should not be misled by a corresponding attempt on the part of the patient. It is far from uncommon for the latter, by persistent silence or even by stout, and seemingly sincere denials, to strive to convince himself as well as his physician that he cannot have hydrophobia. For such is the strangeness of this disorder that, as the old Spartan youth denied all knowledge of the stolen fox which he had hid under his cloak and which was at that moment tearing at his vitals, so in cases of supposed hydrophobia will both patient and doctor try to deceive each other as to what is going on in their minds, the one to save his life, the other to redeem it, until each sees that the other has recognized the poor attempt, and both give it up before the horror which will no longer be held down.

Again, the sufferer with hydrophobia should never be treated with violence. If the disorder be an acute mania, or the fury of a convulsive or febrile delirium, forcible restraint may be required. But it is not needed in hydrophobia. It is true that patients sometimes call for it and doctors often prescribe it. But in both instances this shows the possession of popular, as opposed to scientific, ideas in regard to the subject. Forcible restraint is not demanded for the safety of the bystanders, and it is injurious to the patient. Indeed, there can be no doubt that the greatest struggles of patients who have been subjected to force has been provoked by that very force. The fear of ordinary acts of violence on the part of one supposed to have hydrophobia, is usually supplemented by the fear that a like disorder may be contracted from his bite or the absorption in any way of his saliva. This fear is utterly groundless. There is not one respectable assertion in all the literature of the subject in support of it. I have myself had occasion to put this confidence to the proof, and I have no uncertainty in regard to it. I recommend the attainment of a like confidence to others. For they must be without fear themselves if they would encourage others. And if they have no fear, then they can be of great service at a time when fearlessness seems to be about all that is left to those who would be helpful if they could.

Thus every effort of the doctor must be used to obtain and preserve as great a degree of calm as possible. Then the patient must be disturbed as little as possible. No offer of food or drink should be made. For if a man can live forty days without eating, one may well take the responsibility of yielding to the determination of a patient who not only fears and hates the thought of meats and drinks, but spues them out of his mouth if by any means one succeeds in forcing them upon him.

As to the medicinal treatment of hydrophobia—the less there is of this the better. In most cases there are three ways of administering drugs which are available: by the rectum, by inunction and by hypodermic injection. In many cases medicines can at

times be administered by the mouth. In choosing his remedies and deciding upon the quantity to be given, the practitioner must not be tempted into meeting the violence of the disorder with opposing violence of medication. Whatever plan of treatment be adopted it must be temperate. No use of large doses of morphia, chloral, atropia, curare, chloroform, or such-like, has ever proved of value. Here, if ever, it is the "soft answer" which may be expected to "turn away wrath." I think the use of moderate doses of cannabis Indica may prove useful. Alcohol, in small and repeated doses, taken in hot water, I think might prove a valuable remedy,—it being understood that I presume the exclusion of an inflammatory disorder with hydrophobia merely as a concomitant. I am inclined to think also that something might be expected of the method of "mixed narcosis," proposed for surgical operations, in 1877, by Nussbaum. In this method a dose of $\frac{1}{4}$ – $\frac{1}{2}$ gr. of morphia is injected hypodermically, and in a few minutes chloroform is given by inhalation. If this could be done without too great resistance on the part of a patient with hydrophobia, I believe it would prove very advantageous. These things, then, I would recommend: moderate doses of chloral or cannabis Indica at the very beginning of the seeming development of the disorder; later frequently repeated moderate doses of whiskey or brandy in a little hot water, given by the mouth if possible—and this is oftener possible than most persons would suppose—by the rectum, if necessary. Last of all, the plan of injecting subcutaneously $\frac{1}{4}$ – $\frac{1}{2}$ gr. of morphia (adult dose), followed by the inhalation of chloroform, might be tried. The use of prolonged hot baths I believe may do good, not as a specific, as some have foolishly supposed; but by the activity of the circulation they produce and their invigorating effect.

In all the treatment of hydrophobia, the cardinal principle should be that the medication must be reduced to a minimum. Indeed, I have no doubt that better results than have been attained by any method heretofore recommended would be secured if no medication at all were employed. There can be no doubt that it is true, as Decroix asserts, that the ordinary methods of treatment act adversely to the interests of the patient, and that the rational plan is restricted to two indications: to protect the patients from all causes of excitation; to procure for them all the moral and material satisfactions compatible with their state.¹ "By adopting this method," Decroix adds, "there will be obtained a natural hydrophobia more benign than the artificial hydrophobia, which is a consequence of the incendiary medication, and cases of cure will certainly be less rare than in the past."

Only last year, M. Barthélemy called attention to the suggestions of Decroix, and emphasized them by a reference to the practice of M. Abadie, a veterinarian of the Department of the Loire Inférieure, in the treatment of tetanus in horses. The latter, after observing the lamentable failure of active treatment, adopted with marked success the plan of letting the animals strictly alone in a darkened room, from

which all sights and sounds were rigidly excluded. Further, M. Barthélemy recalls the method adopted by M. le Docteur Bouley¹ to control violently hysterical patients. This consisted in shutting them up in a padded room, from which all light was excluded. "C'était," he says, "ce que notre maître appelait le traitement par astimulation." From this he thinks a profitable lesson may be drawn as to the management of cases of hydrophobia.² This is undoubtedly true, and it seems strange that this obvious indication of the success which has often followed the administration of absurd and inefficient nostrums, namely, that no medication is better than active treatment, has for so many years failed to secure the application in teaching and in practice which it should have had.

In concluding, I would state my belief that the uncertainty and despair which prevail in regard to the treatment of hydrophobia, are to be attributed largely to the commonly held opinion as to the specific nature of the disorder. I have elsewhere stated the conviction to which observation and a laborious study of this subject have led me, namely, that hydrophobia is not a specific, inoculable disease; and that the dread of swallowing, and the other phenomena which are known as hydrophobia, do not indicate a specific morbid process, but are mere symptoms of a variety of disturbances of the animal economy, some of these being of an organic, others of a purely functional (in the usual sense of this term) character.³ This attitude has been so often misstated as a denial of the existence of hydrophobia, that I think it important to say that I do not deny that there is a set of symptoms which, for want of a better name may, without great impropriety, be called "hydrophobia." What I deny is that these symptoms depend upon a specific virus derived from a rabid animal. It is undeniable that the symptoms of hydrophobia may *follow* the bite of a dog suffering with what is called rabies; but so they may, in most typical form, the bite of one that is simply angry, or not angry at all, and quite healthy, or of a man who is simply angry, or they may arise in the progress of a variety of diseases, or spontaneously as the result of fear. In all these cases the phenomena and the issue are exactly the same. There can, therefore, be nothing specific in the saliva of a so-called mad dog, unless the word "specific" be given a new meaning to suit this particular case.

After a very careful study of the literature of hydrophobia from the earliest times, and after some personal experience, I have therefore come to the conclusion that the specific theory is false, and that the view that hydrophobia is merely a symptom and not a disease, offers the only thread which can guide one through the labyrinth of facts and theories, somewhere in the maze of which the truth in regard to it lies hid. Equally do I believe that the adoption of this opinion offers the only hope for a rational and satisfactory plan of treatment. For 2,000 years, or perhaps even longer, the specific theory has had prac-

¹ This physician must not be confounded with M. Henri Bouley, the veterinarian, who is famous for his studies of rabies.

tically undisputed sway in the world, and after all there is not a man of the nineteenth century who can propose a method of treatment, founded upon it, more rational or more efficient than those which were used in the stumbling infancy of the art of medicine. Cælius Aurelianus was as sensible as Dr. Rush, and Celsus was no whit behind Sir Thomas Watson. The most enlightened of its adherents come before the world offering in one hand uncertainty and contradictions, in the other despair. This remarkable paradox I attribute to the fact that, wearied with following the luring *ignis fatuus* of the specific theory, men have come to believe that the nature of hydrophobia is beyond human understanding. The cause of science and the cause of humanity demand, I believe, that we shall let this theory go. It will not be lost. Such things may be trusted to come back. But truth lies at the bottom of a well. And, if we will leave this subject to the generations which shall follow us in a clearer light than that in which we have received it, it must be by sweeping away the marvellous and fabulous features which have come to be accepted as essential parts of it, and by rigorously applying to what is left the well established rules of common experience and analogy. Then, and then only, will it come to be known what hydrophobia is, and how it should be treated.

THE SIGNIFICANCE OF BLOODY DISCHARGES FROM THE BOWELS IN YOUNG CHILDREN.

BY FRANK WOODBURY, M.D., OF PHILADELPHIA.

Read in Section on Diseases of Children, American Medical Association,
May, 1884.

The occurrence of blood in the alvine discharges of a young child, whether in amount large enough to constitute actual intestinal hæmorrhage, or existing only as a few small clots or streaks of blood, is a symptom which naturally excites alarm in the minds of those having it in charge, and usually is the signal for prompt appeal for medical aid. Whether rightfully or not, in an individual case, it may be considered as the rule that this accident in childhood is of much more serious import than in adult life, although in some instances the pathological conditions are identical. On account of the gravity and urgency of the morbid states involved, the opportunity for the exhibition of skill in diagnosis, and the possibility of brilliant results from appropriate treatment, I would regard this class of cases as second to none in interest or importance to the general practitioner of medicine. It was with this thought in mind, that I determined to submit this subject of The Significance of Bloody Discharges from the Bowels in Young Children for discussion to-day. I do so the more willingly because, so far as I can learn, this subject has not been considered at any previous session of this Association, and because many of our text-books

on diseases of children either observe complete silence upon this symptom or make only incidental and altogether inadequate mention of it as complicating certain conditions.¹

Like hæmatemesis, bleeding from the intestines is merely symptomatic; its causes vary greatly in site, nature and gravity. A correct and promptly rendered diagnosis in such cases sometimes furnishes a crucial test of skill in the physician. I need not dwell upon its importance, since we recognize the fact that a few hours' delay may cost the life of the patient. In a case in which the range of remedies is from laparotomy to worm-lozenges, delay and error in judgment are alike dangerous.

The term *Melæna* (*Μελαίνα*) was anciently used to indicate the discharge of a black material from the stomach, or the bowels, or both. Since the action of the digestive fluids upon blood effused into the small intestine, causes it to lose its ordinary physical characters and to change to a black, tarry substance, the propriety of the application of this term to many cases of intestinal hæmorrhage is evident. But, as the blood occasionally preserves its red color; and, on the contrary, black discharges may be due to other causes than hæmorrhage (*i. e.*, the administration of certain substances such as bismuth, animal charcoal, etc.; or, more rarely, to altered secretions from the mucous membrane of the intestinal tract,²) I have preferred to employ the term "bloody discharge," as being more comprehensive than either *melæna* or intestinal hæmorrhage, and being universally recognized as a symptom, will be free from a possible objection on account of being mistaken for the title of a pathological condition.

Blood may also appear in the discharges, from a lesion existing in the stomach, œsophagus, or upper air passages—or even from a source external to the patient, being taken with the food, as when an infant nurses from a cracked and bleeding nipple—but for our present consideration, it will be sufficient to limit the consideration to lesions below the pylorus; and the brief time at my disposal warns me that a few only of the leading diagnostic features of the morbid states concerned can be presented for discussion.

The first question that the clinician, when confronted with such a case, attempts to solve is: What is the site of the hæmorrhage? and secondly: What is its cause? Let us pass briefly in review some of the morbid states giving rise to bloody discharges from the bowel.

Commencing with the lower extremity of the intestinal tube, we recognize several local conditions which may be accompanied by hæmorrhage.

¹It is only just to state that Dr. J. Lewis Smith, of New York, in his admirable work on Diseases of Infancy and Childhood, gives the best consideration of this subject that I have met with among our systematic treatises.

²In a foot-note to the article on *Melæna* in Copeland's Dictionary of Medicine, New York, 1846, vol. ii, page 954, a case is reported of an anæmic child, three months old, which had *melæna* without intestinal hæmorrhage: there were black discharges during life, and found after death along the whole course of the intestines, which was apparently a morbid secretion from the mucous follicles. The condition appeared to be an abnormal excretion of carbon, in some way dependent upon a congenital absence of the gall-bladder and hepatic ducts.

In cases where a doubt exists as to whether the black material excreted contains blood or not, the question may be solved by simply diluting the discharge with water, which will bring out the red color of the hæmoglobin if it be present. The microscope or the spectroscope will furnish the decisive test of the presence of blood.

Venous hemorrhoids may occur in young children. These may be examples of *nævus*, or may come under the class of internal hemorrhoids. Notwithstanding the fact that cases of supposed piles in infants usually prove to be polypi upon closer investigation, Allingham¹ reported a case, in a boy three years of age, which had bloody discharges from the rectum, and upon examination, thin vascular piles were found to be the cause of the bleeding. Sedgwick² and Syme³ have also called attention to the possible existence of piles at an early age of life. Condylomata need not be confounded with hemorrhoids; these are not rare in children, and may be caused by irritation, uncleanness or worms; they are not necessarily due to syphilis.

Fissure of the rectum is a rare cause of bloody discharges in children. Allingham mentions a case in a boy 4½ years of age.

Prolapse of the rectum is less frequently accompanied by bleeding in children than in adults, but it is sufficiently common to warrant consideration. It is usually caused by weakness of the sphincter, following prolonged diarrhoea; or it may be due to constant straining, caused by a reflex irritation, such as from a stone in the bladder, a contracted prepuce, or polypus.

Polypus of the rectum is more frequent in children than is generally supposed, and is usually announced by recurrent attacks of bleeding. Bryant⁴ says that is the principal cause of hæmorrhage from the rectum. Therefore, repeated attacks of intestinal bleeding should lead to a direct examination of the bowel. When found, the polypus may be broken off by the finger nail without inducing hæmorrhage. Its usual site is inside the internal sphincter, from two to six inches within the bowel. The pedicle may be several inches in length. Gross⁵ recommends seizing the tumor with the forceps, if not very vascular, and removing it by torsion; if vascular in its appearance, "the safest plan is to tie it and let it slough off." It is reported that Bryant saw twenty cases, all in children less than two years of age, which were operated upon successfully.⁶

Foreign bodies may cause ulceration and hæmorrhage; various substances, such as pieces of bone, glass, oyster shell, etc., may be forced or impacted in the rectum, either swallowed by the child or introduced into the rectum, by mishap or malice.

Traumatism. Bearing in mind the facility with which fatal hæmorrhage might be induced by wounds of the intestine and adjoining structures, it might be the means employed for criminal purposes. In cases of acute hæmorrhage from the bowel, in a child hitherto healthy, local examination of the part, both before and after death, should not be neglected.

It may be proper to say here that a hæmorrhage may be sufficiently profuse to cause death, may occur without any discharge of blood externally. J. L. Smith

refers to a case (Bidnar) of a boy 11 days of age, in which the skin rapidly became yellow and cool, respiration scarcely perceptible. He died on the twentieth day of exhaustion, and it was found that the symptoms were due to a concealed intestinal hæmorrhage.

In *dysentery and entero-colitis* of sufficient severity, blood will often appear in small quantities in the stools during the height of the inflammation; where it occurs in larger quantities it indicates ulceration, and in chronic colitis the discharges may consist of pure blood. Without stopping to discuss the parasitic nature of ordinary dysentery, I would notice that *mycosis* has been assigned as the cause of dysentery with bloody discharges. Lambl reports the case of a child 2 years old, which died of enteritis and hæmorrhages from its intestines, where *amœba coli* were considered to be the cause. Experiments made by Lösch favor the view that the dysentery in such cases is primary, and that the *amœbæ* appear later and maintain the morbid state. We are without information as to the source of the *amœba*.

Intestinal worms have been mentioned as causing the appearance of traces of blood in the discharges, mixed with mucus.

Intussusception of the bowel, either by descent of part of the ileum through the ileo-cæcal valve, or elsewhere in the course of the bowel, is very commonly accompanied by bleeding. This symptom, in a case of constipation, obstinate vomiting, with tender, swollen abdomen, in which there is a sausage-shaped tumor may be felt in the course of the bowel, indicates the occurrence of an intussusception. In such cases the injection of large quantities of warm water will usually be successful in reducing the invagination. Etherization by the rectum might be useful, followed by distension of the bowel by air. The knee-elbow position will materially assist the enemata in restoring the bowel to its normal relations. Should these measures fail, after several attempts, laparotomy offers better chances of recovery than to wait for the sloughing of the intestine, which sometimes does occur. Although early operation by modern methods of opening the abdomen, generally offers good prospects of success, yet this result can not always be promised. Godlee¹ reports a successful case in an infant of nine months, in two others the patients died. He calls attention to the fact that the intussusception does not always begin at the ileo-cæcal valve; although, according to Bryant, (*loc. cit.*), this is the most common site in infancy and childhood. The condition may be gradually established without interfering greatly with peristalsis and defecation, or it may rapidly give rise to symptoms of complete obstruction of the bowel. Such acute cases have urgent symptoms and require, usually, early operation. In the former, prompt operation is not so imperative. Mr. Hutchinson, of London, opened the abdomen of a child, two years of age, on the thirtieth day of the symptoms, and restored the invaginated bowel with a successful result.²

Ulceration of the small intestine may be due to

sloughing of necrosed follicles in the course of simple catarrhal inflammation, or it may be tubercular in its origin. In the course of tubercular meningitis, tubercular ulcers may occur in the bowel; and in tubercular peritonitis the occurrence of diarrhoea and offensive stools, with the discharge of blood in small clots, is very suggestive of accompanying ulceration of the bowel (Eustace Smith¹).

The occurrence of such a hæmorrhage may give rise to the suspicion of typhoid fever being present, but the clinical history of the case will afford the means of distinguishing the two diseases.

The preceding conditions have been, principally, those referable to definite lesions of the large and small bowel. We shall now consider a few disorders less localized in their nature.

Congestion of the mucous membrane, with or without accompanying catarrhal inflammation, is quite common in young infants, and occasionally causes bloody discharges. This congestion may also be secondary to diseases of other viscera. Mosler states that chronic diseases of the spleen are liable to be complicated with diarrhoea. He also says: "The phenomena of irritation of the intestinal mucous membrane are produced in leucocythæmia and its allied conditions by the accompanying lymphoma. At other times it is a congestive catarrh of the intestinal mucous membrane. The stools contain large masses of mucus and pus, and are not infrequently mixed with blood; dark, tarry blood is evacuated from the stomach, as well as from the intestines. (Ziems en, Encyclopædia, vol. viii, p. 373).

Hyperæmia may be due to disorder of the liver or its imperfect development. Hepatic cirrhosis has been observed in young children, as a cause of intestinal hæmorrhage, by Reynolds,² Murray,³ and others. Weber met with a case in a new-born child.⁴ Occlusion of the portal vein is also noted as a possible cause by Budd.⁵ Embolism of the umbilical vein and its branches causes congestion of the intestines by obstructing the portal circulation. Lederer reports eight cases of intestinal hæmorrhage from this cause, five of which were also accompanied by umbilical hæmorrhage.⁶ Embolism of the branches of the umbilical vein may also lead to the formation of small ulcers in the intestinal tract.

There still remain for consideration the class of cases in which the pathological condition is not well understood. It may be connected with some disorder of the blood. Here may be appropriately considered those peculiar cases of hæmorrhage from the bowel coming on in the first few days of life, generally from the first to the sixth day, which are known as *melena vera* or *melena neonatorum*.

Attention has been pointedly directed to these by Billard,⁷ Croom,⁸ Rilliet and Barthez and others. The following will serve as an illustration: A female

child of healthy parents, born after an easy labor, was apparently well until 35 hours after birth, when an intestinal hæmorrhage occurred, and the little patient died, ten hours later, of exhaustion. At the post-mortem no cause for the hæmorrhage was found; no trace even of organic lesion was detected.¹ In such cases the congestion has been attributed to a plethora, and it has even been recommended that the ligature be removed and some bleeding be allowed from the umbilical cord in order to relieve this hypothetical condition (Billard). It is more probable, however, that the intestinal congestion is caused by collateral hyperæmia associated with some disturbance of the lungs or heart; for Ebstein has found that suspension of respiration in animals produces congestion and extravasation of blood and ulceration in the mucous membrane of the alimentary canal. Of twenty-two cases reported by Rilliet and Barthez, twelve recovered. Probably, as suggested by Day, some of these were cases of pressure of the child's head during tedious labor, and congestion of the venous system from the difficulty in establishing respiration at birth.

Cases of enterorrhagia attributable to *hæmophilia* have been published by Laycock,² Sedgwick,³ Gould,⁴ Huss,⁵ Cousin,⁶ and others.

In such cases the peculiarity is generally known to exist in some other member of the family.

Some cases of *melena neonatorum* seem to be really due to *purpura hæmorrhagica*; and a number of authorities have given weight to the opinion that in others it may be due to a general cachexia, associated with syphilis. There is good reason for doubting, however, that syphilis in the parents can cause the hæmorrhagic diathesis in the child.⁷ Such cases are probably secondary to disease of the blood-vessels, or liver, or both.

Blood sometimes occurs in the discharges during the specific fevers from congestion or ulceration of the mucous membrane. It is only of late years that typhoid fever has been generally acknowledged as occurring in infancy, although Rilliet called attention to it in 1840. (Thèse de Paris, 1846).

Typhoid fever sometimes occurs within the first year of life, but is rare until after the expiration of the second year, being more frequent between the ages of eight and eleven years. Still, Meigs and Pepper have met with well-marked instances at the age of 18 or 20 months.⁸ Typhoid fever ulceration being unusual in children, this must be a very remote cause of the appearance of blood in the discharges.

Attention has recently been directed to cases of visceral rheumatism in the adult. I met with a case last year in a child, which I may briefly mention. It was that of a boy about 8 years of age, who, during the progress of an attack of acute articular rheuma-

tism, at about the fifth day was seized with obstinate constipation, with discharge of blood from the bowel. This, with the occurrence of vomiting of everything taken into the stomach, even of small quantities of ice-water, and great restlessness, led me to suspect intestinal obstruction. A tender spot was found in the left hypochondrium and near the umbilicus, but no well-defined tumor was detected. He was treated by morphia by the mouth, and by large hot water enemas, which were returned tinged with blood. The third or fourth injection was followed by fecal discharge, and the condition was relieved. The patient recovered finally, and was seized with chorea during convalescence. If there was actually an intussusception in this case, I believe that it was favored if not caused by a local manifestation in the intestine of the rheumatic poison.

I trust that in bringing to a conclusion this hasty review of an important subject, we are impressed by the variety of the conditions upon which these bloody discharges may depend, and especially by the necessity of careful physical explorations where the symptom persists.

DISCUSSION.

Dr. J. Lewis Smith said the pathological state is different in the different diseases. The most frequent and common causes (when not mixed with mucus) are purpura hæmorrhagica and intussusception. The latter is an important matter. There is none more important in diagnosis. This occurs chiefly at the ileo-cæcal valve, or it can occur at some point below, become wedge-shaped, congested, and blood oozes. There are two common points. These may either be at lower part of ileum or in the colon. Congestion becomes so great that hæmorrhages occur. The color of the blood is dark-red, with mucus. When tenesmus is present, it can be mistaken for dysentery. Instead of mucus, pure blood can be discharged every few moments with tenesmus. This disease must be recognized early, as the diagnosis is of importance. In these cases, warm water injections into the rectum is good treatment. The diagnosis can be made without a tumor being present, by blood appearing without mucus.

The next principal cause—*morbus maculæ* or purpura hæmorrhagica, is most common in large cities and hospitals, among broken-down and cachectic children, but is also found in well nourished ones from six to eight months old. The changes occur in the capillaries and not in the blood. This is the true condition, as is proved by microscopical examinations. Blood is allowed to transude. Knows no case where hæmorrhages resulted from worms, but this could take place where the bowels were ulcerated and the worms irritated the places so diseased. Typhoid fever occurs in children, but ulceration in children, as a rule, is not sufficient to give rise to hæmorrhages. In the majority of these cases there is no tenesmus.

Dr. S. S. Adams said that Dr. Woodbury failed to bring out the important point of the dangerous period of these bloody discharges. He said that the cessation of the bloody discharges was really the signal of danger. He said that some time since, Dr. Busey wrote an admirable paper on "Thrombosis of the

Sinuses of the Dura Mater in Fatal Cases of Dysentery in Young Children," in which he showed that when the blood ceased to appear in the stools, then the critical moment arrived. Dr. Adams had superintended the post-mortem examinations made in the cases cited, and, as Dr. Busey had expected, thrombi were found in the sinuses. In such cases as Dr. W. had cited, the stimulation should be begun early and diffusible stimulants freely administered. In young children, the fontanelle is our guide. So long as it is depressed, we need have no fear in freely stimulating. Whiskey, camphor, or ether should be given.

Dr. Fry remarked that he had noticed during attacks of entero-colitis, that the occurrence of hæmorrhage from the bowels marked a favorable epoch in the disease. It probably acted by depurating the congested mesenteric vessels.

Dr. Woodbury. The time was not long enough to go into the subject more closely. Would recommend digital examinations in all cases.

ON THE TREATMENT OF TYPHOID FEVER.

BY S. K. JACKSON, M.D., NORFOLK, VA.

Read in Section on Practical Medicine and Materia Medica, American Medical Association, May, 1884.

My apology for occupying the valuable time of this Section must be found in my conviction of the importance of the subject I propose to discuss. I know it is thought trite and hackneyed, but the discussion of it cannot be considered as finished until there be a better agreement among us as to the treatment of this disease, or until the mortality from it is diminished much below its present rate. It is claimed to have been reduced from the 18 to 20 per cent. of a half century ago to 10 or 12 per cent.; but these lowest figures are still too high, and it is to be hoped that the profession will not be satisfied until there is a much greater reduction.

My object is not to boast of any great success in managing this disease, but merely to call attention to a line of treatment which has furnished results very different from the recorded experience of others; a treatment suggested by the recognition of several pathological conditions, which, though long since demonstrated and, I believe, generally admitted to exist, have been entirely ignored by the profession when looking for indications of treatment.

To prove this assertion it is only necessary to enumerate the various means at different times resorted to for combating this disease; means not only not indicated or called for, but oftentimes actually injurious.

The limits of this paper will permit me to recall but a few of them. Blood-letting, urged by Louis—free evacuations—tartarized antimony—calomel—then the "expectant" plan of treatment, the do-nothing plan, leaving all to nature—then follows the suggestion of phosphoric acid as a febrifuge—next came the alum treatment of Barthéz—then the confi-

dent assertion that large and repeated doses of quinine was the one thing needed—then came the announcement that the latter did no good, but actually did harm—next occurred a revival of the mercurial treatment pushed to salivation—then turpentine is lauded as the remedy—then succeeds a revival of quinine in large doses, with conflicting testimony *pro* and *con*; some asserting that it produced alarming prostration, others claiming it as valuable for reducing temperature. Next looms up the hydropathic treatment, by many lauded, but considered by others to be liable to grave objections.

While all this conflict has been waged, I have been pursuing one plan of treatment for the past thirty-five years, from which I have not had any reason to deviate; and there is not included in it one of the suggestions contained in the above enumeration. The result of this plan I am reluctant to state, its value any one can determine for himself.

Among the first and most prominent pathological states which early attracted my attention as furnishing indications of treatment, was the demonstrated nitrogenous waste of the system—the diminution of fibrine—the deficiency of urea, and all nitrogenous excretions. If it were not the case that there was a deficiency of the nitrogenous constituents of the blood, it might be supposed that these excreta were retained in the system as in the case of desquamative nephritis, but their absence is evidently due to the fact that there are none to be thrown off; we have no signs of uræmic poisoning, even the coma of enteric fever has never been attributed to that cause.

Into the cause of this nitrogenous deficiency I cannot now inquire, but will only suggest one or two probable factors.

The first is an inability to digest nitrogenous food, caused by a deficiency of the digestive fluids, which deficiency is due to the fact that all the glands and glandular follicles whose duty it is to secrete these fluids, are in such a state of engorgement or inflammation as to render them incapable of performing their function.

Another possible, if not probable, cause of this nitrogenous waste is due to the consumption of this important element by the parasitic organism which is the acknowledged etiological factor in the production of enteric fever. That this microzoon is a nitrogen-feeder, is evident from the fact that he lives and is developed in nitrogenous matters, in urea and all nitrogenous excreta. These furnish its peculiar pabulum, in them it is generated and thrives. Old timbers saturated with urea, the rotted logs of a country cabin against which men have constantly micturated, have been known to be fruitful sources of this disease. The most serious outbreak of typhoid fever I have ever known, occurred during our late war (1862) in a Mississippi Brigade, who were encamped at the foot of a mountain-slope where a large amount of leaf-mould had been for years accumulating. This spongy mass when saturated with their urinary deposits, and probably in a state of fermentation, caused the most malignant epidemic of this disease that has occurred in my experience. I

hope, some day, to obtain access to the official records to ascertain the great numbers who fell victims to it; they are numbered by hundreds. I hope I may be pardoned for mentioning here, that of 223 cases that were taken under the treatment I am now advocating, not one died. The Brigade alluded to, that of Gen. D. H. Hill, encamped at the foot of a spur of the Catocin Mountain, two to three miles northwest of Leesburg, Loudoun Co., Va., within forty miles of where we now stand.

If further proof be needed that this microzoon is a consumer of nitrogen, it is furnished by the ammoniacal exhalations emitted by a typhoid fever patient, from the breath, the skin, as well as by the urine, which, when freshly passed, as is known to all, emits the odor of ammonia, like stale urine in a state of decomposition.

These exhalations are undoubtedly due to the decomposition of the nitrogenous constituents caused by this micro-organism.

This pathological condition, in my opinion, furnishes us with the most important indication in the treatment of this disease, and has shaped my practice during the long period mentioned.

It is clear then that our aim should be to supply this nitrogenous waste. How is it to be done? By nitrogenous food, you will say; a very rational way of accomplishing that desirable end, were it not for the utter impossibility of digesting and assimilating this food, to which we have already alluded. There is only one way, known to me, of effecting this purpose, and that is by the free administration of AMMONIA, even to saturation.

Fortunately, this nitrogenous base furnishes us with salts of such different therapeutical powers that we have no difficulty in finding one adapted to any and every stage of the disease and every probable condition of the patient during its existence or progress. It supplies us in the nitrate with the most sedative salt we possess, and in the carbonate, with the most stimulant salt in our *Materia Medica*. The only other salts of ammonia I have been in the habit of using in the disease are the acetate and the hydrochlorate, in conditions which will be presently pointed out.

The high febrile condition of the early stage, high pulse, high temperature, etc., calls imperatively for the nitrate, which in 10 or 12 gr. doses will reduce the highest temperature I have met with, down to about 102° F. At this degree, which is not a dangerous heat, it can be kept during the whole course of the disease.

It is to be expected that there may be some fluctuation in this contest between the heat-producing and heat-allaying agents, but I have never known an instance in which, during the administration of this salt, the temperature rose again over 103°, after having been once reduced.

As the disease progresses, when there is less demand for so powerful a sedative, especially if diarrhoea supervene, I substitute the acetate for the nitrate of ammonia, and administer at the same time acetate of lead and opium. If nervous symptoms show themselves, tongue incline to become coated, teeth dry

and covered with sordes, I resort to the carbonate of ammonia in combination with potassa chlorate; and should coma occur, my sheet anchor is the hydrochlorate of ammonia, which I have never known to fail in bringing a case out of that condition.

But I must remark here, that I have seldom (I might say never) seen coma occur in a case where the treatment, detailed above, has been energetically pursued; and it has been mostly in badly nursed cases, or those under a different course of treatment, that I have seen it at all. I have known them to be brought out of it when apparently almost in *articulo mortis*, when all treatment had been stopped and the case relinquished.

With regard to the delirium, which I have always considered as due to a want of nourishment of the brain, the delirium of starvation, it is soon quieted and controlled after the inauguration of this ammoniacal treatment.

I remember a case of a young man, who was found by his friends near the army, about 200 miles from his home, in a state of wild delirium, and in this condition brought home far advanced in the disease, and who became quieted in twenty-four hours, and made a good recovery. If wanderings occur during the treatment, it is owing either to too small doses, or to too long an interval between them. I have known patients to request that the doses be brought closer, on account of a confusion of mind they felt towards the close of the interval between them.

The tympanitis, as everyone knows, is easily relieved by turpentine stupes, turpentine enemata, or by a few drops of turpentine regularly administered by the mouth. With regard to the use of hydrochlorate of ammonia in the state of coma, it suggested itself to me as a solvent for the thickened envelopes of the blood-corpuscles, which some pathologists contend exist in this state, preventing the nourishment of the brain even if the blood were in an otherwise normal condition. Whether this be its *modus operandi* or not, the effect of it is almost miraculous in this condition.

Thus it will be seen that there is no period, no stage of the disease, in which I am not administering some one of the salts of ammonia. Why should I resort to cold baths or cold effusion to reduce the temperature, when I can bring it down and keep it down by means so much simpler, more certain, safer and more philosophical, and not liable to a consequent reaction?

With regard to quinine, I have years ago abandoned it, from the full conviction, in which I agree with Professor Bartholow, that it is not an efficient germicide in this disease. I recognize it as, *par excellence*, the antidote to the malarial poison; but since the organism producing enteric fever differs so essentially from this, it requires for its destruction a germicide of an entirely different character. I have shown this parasite to be a nitrogen-feeder, and an exhaler of ammoniacal gas; but that which produces the malarial fevers is a carbon-eater, and exhales carbonic acid gas. It is not to be expected, then, that the same agent would be equally efficacious in destroying both.

The subject of the selection of germicides has not

been studied as its importance demands, and I know no more interesting or profitable field for cultivation. The germ theory of disease has necessitated new lines of treatment, and the application of new remedies, or old ones with new intent. The investigation of the causes of diseases is running ahead of the study of the means necessary to destroy them, whereas it is of the highest importance that they should progress *pari passu*.

In a paper recently read before the Virginia State Medical Society, I have contended that we are furnished with a key to the detection of our germicides by a law, which, as far as I know, I have been the first to enunciate. I claim that it is a law that no organism can live in its own excreta, in the products of its own vital processes. When carbonic acid gas is the excretory product, how certainly does carbonic acid destroy the life that produced it. If alcohol be the result of the life-process, what better agent have we for arresting that process than alcohol itself, and how generally is it used for that purpose. If sulphuretted hydrogen be the exhaled excretion, all acknowledge the efficacy of sulphur and its compounds to arrest the decomposition giving rise to it. So, also, if ammonia be the result of the vital processes of an organism, as we have claimed in the case of typhoid fever, then by this law we have a right to infer ammonia to be the proper and efficient germicide. This furnishes us with an additional indication for employing the salts of this nitrogenous base, for it not only supplies the nitrogenous waste, as we have contended, but also destroys the vitality of the organism which causes it.

On this principle we would select quinine, on account of the large quantity of carbon it contains ($C_{20} = 240$, $H_{24} = 24$, $N_2 = 28$, $O_2 = 32 + H_2O$), as the germicide for an organism the excretory product of whose life is carbonic acid gas; but never for an organism whose excretion was ammoniacal gas (NH_3). We see then why it is that quinine is not an efficacious germicide for the enteric-fever parasite, and how it is that ammonia fulfils the two important requirements mentioned above.

If this be a law, as I have stated it, may not the protection of the system from a second attack of contagious diseases generally, be accounted for, not on the almost universally received theory that the system during the first attack becomes exhausted of the pabulum necessary to the life and development of the parasitic organism producing these diseases; but rather to the hypothesis that there is left in the system during the first attack, some excretory product which, being never eliminated, forever thereafter acts as a poison to that organism, inhibiting its vital processes. This appears to me to be the most probable and most philosophical explanation of this mysterious fact.

My experience with this fever when treated by the plan here pointed out, enables me to expect that if a case be recognized as one of enteric fever within three days of its inception, that it may break at the end of the 1st septenary. If it be not recognized as such until the 4th or 5th, it can not yield before, but may at, the end of the 2d septenary (14th day).

If the treatment has not been commenced before the beginning of the 2nd septenary, the fever can not break before the end of the 3rd septenary (21st day); that it will yield on that day, if it has not yielded before, is almost an absolute certainty.

With regard to *diet*, nothing has so surprised me as to see recommended articles of food which for years I have most sedulously avoided, because of having seen them do infinite harm in this disease.

How a physician who has had any experience with this form of fever can recommend farinaceous or starchy articles of food, I am at a loss to understand. The disturbances they occasion, which must have been noticed by every one, have given me more trouble than anything connected with these cases. They are easily understood when it is remembered how entirely absent are the salivary fluids, or any of the fluids containing diastase, by which is prevented the conversion of amylaceous food into dextrine and grape sugar. Such food therefore is not capable of assimilation, but soon after its admission into the stomach undergoes a fermentation which adds to the gaseous distension which may have occurred from other causes, and seriously complicates the case. I regard milk not only as the safe, but as the only useful article of diet, and this I allow *ad libitum*. Even if a larger quantity is taken than can be assimilated, it does no harm, though it is often passed unchanged.

I have never allowed the animal broths in the early stages of the disease without having reason to regret it. So that my plan is to allow nothing but milk, until such time as I perceive evidences of a return of the secretion of the digestive fluids. The chewing of lean meat, swallowing only the juice of it, is a favorite way of returning to animal food, as the act of mastication may stimulate the flow of the salivary fluids.

I fear that the limited time allowed me has compelled such a condensation of so extensive a subject, as to make my paper unsatisfactory. It must be considered, however, merely suggestive, as I have been able only to hint at the salient points of treatment, leaving it to the ingenious practitioner to fill up the details.

Hoping that this treatment of this serious disease may prove as successful in other hands, I leave it with you for trial.

MEDICAL PROGRESS.

MATERIA MEDICA AND THERAPEUTICS.

ON THE THERAPEUTIC DIFFERENCES IN ELECTRIC CURRENTS, AND ON THE ELECTRO-DIAGNOSTIC EXPLORATION OF THE EXTENT OF THE FIELD OF VISION.

—C. Engelskjön has an extended article on this subject in the *Nordiskt Medicinskt Arkiv*, which is summed up as follows:

1. The experiences with patients suffering from cutaneous vascular neuroses, have demonstrated that in their local application upon the skin of the subject, with the use of the electric water bath, the two forms of electric currents exercise an inverse action

upon the vessels, in that the faradic current dilates the vessels spasmodically contracted, while the galvanic current contracts the vessels that are actively dilated. In conformity with this difference of action, the faradic current produces simultaneously an increase, and the galvanic current a lowering of the temperature. There is no difference in the two poles of the galvanic current.

2. The central application of electricity produces similar effects, in cases analogous to the cutaneous vascular neuroses, so that in certain given cases the relief is due to one only—that is to say, either to the faradic or galvanic current.

3. Comparative observations on patients suffering from *hemicrania and other central neuroses*, have demonstrated that in proper applications the galvanic current acts inversely to the faradic current, in a therapeutic point of view, as one of these currents only will give relief in a case where the other increases the disease. The difference in effect of the two currents upon the subjective symptoms, is in most cases instantaneous and marked. It is possible to neutralize the effects of one by the other.

4. The neurotic affections of the great sympathetic, such as stenocardia, cardialgia, etc., act with reference to electric currents, similarly to the affections of the central nervous system.

5. The author has noted cases that, beyond a doubt, from their clinical condition, were affections accompanied with evident anatomic alterations of the central organs, and which, nevertheless, yielded to treatment in the same way as the neuroses, and were promptly relieved by suitable electric treatment.

6. It is more than probable that the peculiar etiological nature of these cases exercises a determining influence upon the consequent condition of the case in particular, and consequently a knowledge of the etiological conditions in a case is necessary to a suitable selection between the two kinds of current.

7. A diseased condition of the spinal ganglia may act reflexly upon the spinal cord, and give rise to spinal symptoms. In the same way spinal affections are capable of reflex action upon the brain, and of giving rise to cerebral symptoms. Reflex actions proceed *always* from below upwards. It is well to observe here that the organ secondarily influenced by the reflex action should generally be treated by a different current from the organ in which the affection has its origin.

8. The author treats cerebral symptoms by electrization of the medulla oblongata. He places one electrode in the fossa of the ligamentum nuchæ, and the other above the larynx. The spinal symptoms can be treated simply by conducting the electric current along the lower portion of the spinal cord.

9. The increase of morbid symptoms that is provoked by a long-continued use of electricity, so well known, is due to the effect of the current on the healthy ganglionic cells.

10. The electrization of the brain, of the spinal cord, of the ganglia and skin, exercises a powerful influence on the functions of the retina, by, in a given case, the positive current increasing the field of vision, and frequently at the same time increasing

markedly the acuteness of vision. As these effects are, so to speak, immediate, it is possible to utilize them in determining which current is suitable to the case.

11. If we subject for several minutes the hands and fore-arms to the action of warm or cold water, in special morbid cases, the same effect is produced upon the field of vision in the use of the cold water as with the galvanic current, while the warm water produces the same effect as with the inductive current.

12. In their general action on the skin, the cold and warm water exercise, in certain given cases of disease, the same therapeutic effects as the galvanic and faradic currents when used separately, the effects of cold water resembling that of galvanism, and those of warm water being identical with the effects of faradism. If we know the kind of current best suited to a given case, we can indicate the water treatment. *Vice-versa*, the effects of water will indicate the selection of the electric current.

13. There are cases of nervous affections which, while suitable for general electric treatment, are not benefited but made worse by the use of either of the currents in central electrization. It is always possible to relieve a certain number of these cases by electrization of the skin. So employed, the electricity acts in two different ways: 1st, by influence upon the skin itself; 2nd, by influencing the peripheric nerve canals. The two forms of current act inversely in the first case, but not in the second.

14. In using the two currents upon the peripheric nervous circuits in neuralgia, the author has never observed any qualitative difference in their therapeutic activity.

OBSTETRICS AND GYNÆCOLOGY.

URETHRAL ECTASIA OR VAGINAL URETHROCELE.—Professor Santesson describes (*Nordiskt Medicinskt Arkiv*) a case of this rare affection of the female urethra as occurring in a seamstress, 48 years of age, who had passed through two difficult labors, without the use of the forceps, however. The last labor occurred twelve years previously, and from that time she dates her trouble. The first symptoms were itching and heat of the vagina, pain in that organ during coitus and while working, in connection with difficulty in urinating and alternating retention and incontinence.

On examination, the anterior wall of the vagina was found to be depressed at the entrance to the vagina, above and behind the promontory of the urethra, where there was a regular elastic tumor of the size of a walnut. The rest of the vagina and the uterus were in no way abnormal as to size or position. The tumor consisted of a pouch about 3 cm. long, and 2 cm. broad, communicating with the urethra by an opening situated at the junction of the superior with the middle third of the urethra, allowing the passage of a sound of medium size (16). Pressure on the tumor seemed to pass the urine, not to the external meatus, but back to the bladder. A catheter passed readily in the usual way into the bladder, if its point was turned downwards it entered the pouch and would pass no further. If the

desire to urinate was not immediately responded to, the urine dribbled away involuntarily, causing acute pain. The urine was of an acid reaction, sp. gr. 1.014, and mixed with a little mucus, but not otherwise abnormal.

Private matters not permitting the time necessary for an operation, the parts were cauterized with nitrate of silver and then with fuming nitric acid, resulting in an eschar which diminished the volume of the tumor, and relieved the incontinence of urine. Three and a half years later the patient returned to the hospital, when an elliptical excision of a part of the vaginal mucous membrane was practised, the edges placed in apposition and united by sutures. Sloughing of a part retarded the cure, but the cicatrix was larger and stronger in consequence. In five weeks' time the wound had healed, and the tumor, firm and contracted, appeared like a solid tumor of the size of the finger. For the four years following there was perfect continence of the urine through the night as well as in the daytime, but negligence and bad habits produced the symptoms anew, and the patient died in the hospital with a puffed and cachectic expression of countenance, œdematous extremities, urethrocystitis and chronic nephritis, and besides specific ecthyma of the trunk and extremities.

There are, in the knowledge of the writer, but six cases of this affection on record, three in France (Toucher, Gillette and Duplay), two in England (Priestly and Lawson-Tait), and one in Germany (G. Simon). The diagnosis does not seem to be difficult, and it can only be confounded with cystocele, which would readily be excluded after a thorough exploration.

With reference to origin and etiology, there are two groups, the congenital ectasias and the acquired ectasias. The first group is not considered here; in the acquired ectasias, there are those formed by a partial dilatation, but more extensive, less closely defined, in a urethra which is normal in other respects, and without a solution of continuity (*diverticula vera*); and those due to a preëxisting cavity (abscess, cysts) situated outside of the urethra, piercing its walls, and in direct communication with it by an opening (*diverticula spura*). The author calls especial attention, in considering the causes of *diverticula vera*, to the effect of a sudden, intense and somewhat continuous pressure upon a canal surrounded by muscular fibres, as producing atrophy and want of resisting force in the circular fibres of the urethra. The cases already published give the histories of difficult labors, the use of instruments, etc., which could result in contusions and injuries to the parts.

MEDICINE.

SUCCESSFUL TRANSFUSION OF BLOOD IN A SEVERE CASE OF UTERINE HÆMORRHAGE.—M. Victor Vlemminky reports a case of this nature in *L'Art Médical*. The details are somewhat lengthy, but they are so admirably recorded and of so much interest, that a perusal of them may well repay the trouble.

The case was one of a prostitute, 25 years of age. On April 4 her courses came on, but she continued her occupation, until, as the result of so much sexual excitement, the flow of blood became so serious as to cause her to enter the hospital April 15 for relief. She had a continual flow from the vulva, and every three or four times in the twenty-four hours, she half filled the chamber with liquid blood—no clots. She had already been submitted to the ordinary treatment, the applications of ice over the abdomen, dorsal decubitus, absolute rest, food scanty and cold, and the use of perchloride of iron and of ergotine. This was the third time within a year that she had entered the hospital from this affection, and each time it was due to the same cause. The first time she remained seven weeks, the second time she remained four weeks before being completely relieved. As to her antecedents, she was always well, had a child when 20 years of age, and from the date of her discharge from the Maternity Hospital, had pursued her present occupation. Two years previously she had suffered from gastro-duodenitis with very marked icterus. There was cardiac steatosis, due, no doubt, to the excess in drinking which had produced the gastro-duodenitis.

On entrance she showed a very marked pallor of the skin, flabbiness of the muscles, great paleness of the mucous membranes, pronounced anæmia, coldness of the body, and especially of the extremities, small depressed pulse, general fatty degeneration. No organic alteration of the uterus, cervix thick and soft, no pain in the hypogastrium. The treatment of ice-bags, constantly applied, absolute rest and dorsal decubitus was continued. The appetite was almost gone, the patient taking only a little cold bouillon and iced drink.

April 17 and 18, the hæmorrhage remained the same. April 19, there was a ringing in the ears with vertigo, no nourishment. Revulsives and styptics were without effect, the hæmorrhage increased. April 20, the patient's pallor is alarming, has fainted for several minutes, has a constant tendency to faint, the slightest movement about the bed is disagreeable, a conversation carried on in a voice somewhat raised is excessively disagreeable. Pulse irregular 108, temperature reduced from 98.6 to 97.3 with oscillations. Auscultation gave a heart-sound like the mixture of air and liquid passing through the auricles and ventricles—a gurgling sound. The patient was completely exsanguine. The feet and hands were icy, the tongue, lips and conjunctivæ perfectly colorless. The pulse became less and less perceptible. A drop of blood under the microscope showed red globules, not deformed but not disposed to group themselves in piles. The proportion as counted was one white to every twenty red corpuscles. April 21.—The foot of the bed had been raised to assist in preventing fainting, but the symptoms continued, one fainting fit lasting 10 minutes and the pulse being 116 and hardly perceptible. M. Poucelet, the interne of the service, offered himself to be used in the process of transfusion, the blood used was defibrinated and filtered, microscopically the red globules were normal, there being one white to four hundred red.

The first attempt at transfusion was practiced upon the leg, but failed because a vein could not be obtained large enough to admit the passage of the canula. The arm was then tried, and fortunately the right median basilic vein admitted the canula. In twenty minutes, proceeding slowly and gradually, 215 grammes (or 37 fl. ounces), of new blood had passed into the veins of the patient, and in an hour's time the operation was over and the wounds closed by carbolized dressings. There was no pain or discomfort expressed, as the blood penetrated the organism, and when about 25 grammes of blood had been injected, the pulse increased in force and amplitude, it still beat irregularly at 128. At the end of the operation the pulse was 116.

The operation was completed at 11:30 A. M., at 12:20 P. M. a rigor set in which lasted until 2 P. M. The patient shivered, her teeth chattered, there was constant subsultus of the muscles, there were dark rings about the eyes and as far as the cheek bones, the naso-labial fold was excessively deepened, and the nose, the lips and the chin were dark like the ring about the eyes. At times there were painful sensations of heat. Pulse very irregular. Respiration frequent and jerky, skin cold.

At 2 P. M. the rigor ceased. Temperature 102.°5. Pulse, 144. At 3 P. M. the patient asked for something to eat, which was given every two hours until 9 P. M. At 4 P. M., temperature 102°, at 6 P. M., 100°, with a pulse of 112. Through the night at three visits the temperature was 99.°5. The pulse became regular and the oppression in breathing ceased. The patient did not sleep, but she declared that she rested, as her head did not feel so empty. *The uterine hæmorrhage stopped entirely.*

April 22, A. M.—Pulse 108, temperature 99.°5. Takes considerable nourishment. Feels contractions in the lower part of the abdomen, like labor pains. Discharged 600 grammes of urine with a density of 1025, urea, 9, gr. 64, chlorides 3 gr. 90, phosphates 1, gr. 50. Slept well that night, perspiring freely.

April 23, A. M.—Temperature 99.°5, pulse 104, well nourished.

Microscopical examination of the blood showed a notable increase in red corpuscles, normal in form and nummular in arrangement, also a number of young hematies and the debris of destroyed red globules. The urine 325 grammes at 1026, contained urea 8 gr. 26, chlorides 2 gr. 58, and phosphates 0 gr. 67, was markedly green in color, and gave a carbolic acid reaction. The carbolized dressings were discontinued.

From this date (April 23) to April 26, the record is given fully, showing a progressive advance to convalescence. April 25, an enema was given, bringing away hard fecal masses with much colicky pain. On April 26, the temperature was normal, pulse full but somewhat accelerated; 1320 grammes of urine, density 1023, urea 20.39, chlorides 19.14, phosphates 2.65.

The interesting points here are the immediate cessation of hæmorrhage after the transfusion of 100 grammes of blood, the marvelous rapidity with which a completely exsanguinated organism was relieved, and the perfect immunity of the operation itself.

CHEESE—CAN IT BE RENDERED MORE SATISFACTORY AS AN ARTICLE OF DIET?—The *British Medical Journal* of June 14, in an editorial on "the dietetics of cheese," gives what seems to be a running abstract of a lecture by Mr. Matthew Williams, on the peculiarities of cheese as a food. The claim is made, consistent with general observation, that twenty pounds of cheese contains as much nitrogenous matter as sixty pounds of meat, and the reason assigned why it has not met with more general approbation is that it is not so easily digested. Then we are told that the reason why it is not easily digested is "because the salts of the milk were left in the whey when cheese was made with rennet. These, especially potash, were most necessary to assist digestion, and food which did not contain them should not be taken alone. Reasoning upon these two scientific truths, he had made a number of experiments as to various ways in which cheese might be made digestible. Casein itself was not indigestible, because it was taken with advantage by infants, and in milk there were two salts which were necessary to nutriment and easy digestion. His aim in the experiments he had performed, was to bring these constituents together, and see what nourishing and palatable foods could be made from them. By putting a sixth of an ounce of bicarbonate of potash with a pound of scraped cheese, and adding to them a small quantity of milk, he found them to dissolve and assume a liquid form. He used double Gloucester cheese in this instance, and the experiment was most successful. With American cheese it was not; and from this fact he was led

to presume that double Gloucester cheese was made with rennet, as it ought to be, while the American cheese was not."

We do not intend to take up *seriatim* the various subjects referred to in the above extract. We have copied it in order that we may not do injustice to our contemporary. When we are told that the salts of the milk are left in the whey when the cheese is made with rennet we are led to infer that there is some other preferable way of making it without rennet, by which the desired salts are retained in the cheese. At the close of the extract we learn, however, as with the addition of the potash the double Gloucester dissolved, whilst the American cheese did not, the conclusion was that the "double Gloucester was made with rennet, as it should be, whilst the American cheese was not."

Now, as Americans we have been charged with a great many abuses; making wooden nutmegs, artificial eggs and the like, but it had never occurred to us that we were ever guilty of trying to find anything cheaper than rennet for the manufacture of cheese. We have nevertheless made some enquiries, and we find that the insinuation is as groundless as the reasoning is illogical.

We have to admit, however, that the charge made against the American factory cheese of insolubility is to some extent true, not, however, from the substitution of something else in the place of rennet as asserted, but by reason of a peculiarity in the mode of manufacturing. In American factories the milk to be made into cheese is always curdled with rennet. It is a peculiarity of the American factory system of cheese making that the curd is permitted to remain in the whey till the latter is distinctly sour. This greatly impairs the solubility and digestibility of the curd and cured cheese, by dissolving out more or less, according to the acidity, of the mineral matters of the curd, and carrying them off in the whey. But by far the greater part of the salts thus dissolved out consist of phosphates which are first converted into phosphoric acid, and lactates of the various bases, and then held in solution in the whey. The advantage which the manufacturer obtains from this procedure is a firm, solid cheese in a shorter time, and the disadvantage is felt by the consumer both in the inefficient assimilation, and in the development of dyspepsia and constipation with their associated evils, moral and physical. This, however, reacts with justice on the manufacturer, and diminishes the sale of an article that might otherwise be in much greater demand. Professor L. B. Arnold, of Rochester, N.Y., in his evidence before the Select Standing Committee

of the House of Commons at Ottawa, says: "It is rare indeed that any one can partake at all freely of such cheese (referring to the sour whey system), without soon suffering from its notorious tendency to constipation, and a general disturbance of the whole system. These effects are so uniform and frequent that people very naturally suspect they are the legitimate consequences of eating any cheese. This, however, is not so. It is only the effect of imperfect manufacture and curing. When properly made and cured, cheese is as healthy as other food, and can be as freely used by the average citizen, and even by invalids with impunity, and so far from having any constipating tendency, is rather a laxative." If these statements represent accurately the relation of the cheese question to the human economy, we trust that our hygienic workers will study the question for us who are consumers, and at the same time make the manufacturers realize that the common interest of both consumer and producer lies in the delivery of a readily digestible article. It is just as criminal to manufacture an article of common consumption carelessly, and thus injure the health of the community, as it is to adulterate an article with a baser product.

IMPORTANCE OF PURE WATER.—Chicago is supplied with water from Lake Michigan. It is taken two miles from shore and conducted to the city in tunnels. When unpolluted by sewerage the lake water is remarkably pure and pleasant. The sewerage of the city is, however, emptied into it through the Chicago river. In the spring, when the river is full, there is sufficient current to carry the sewerage far out into the lake, and when the wind blows from the south, the current is blown directly across the source of water supply. Except for a little time in the spring the river is so sluggish that the water would be motionless unless artificially moved. Some years ago it was found necessary to create an artificial current. In order to do this, two pumping works were established, one on each branch of the river. The river is somewhat Y shaped, the base of Y being the mouth, one branch running south and west and known as the south branch, the other north and west and known as the north branch. It divides the city into three divisions and forms for them an open sewer. Before the artificial current was created, the river during the summer months was a public nuisance. Now, so long as the current is maintained, the river remains salubrious. The pumps on the south branch transfer the water by way of the canal into the Illinois river. Those on the north branch empty it through a tunnel into the lake.

The pumps are made so that the water can be either pumped from the river into the lake or the lake water into the river. However, if a strong current is forced out of the river the water supply of the city becomes polluted. Therefore the south branch is emptied into the canal and the natural direction of the river current reversed. The water of the north branch is pumped into the lake and is now a source of pollution to our drinking water. The engineers say that the current can not be reversed while the south branch pumps are forcing the water out of the river into the canal without causing a stagnation of the water in the main river because of the contrary currents in the two branches.

On the south branch water is being pumped from the river at the rate of 60,000 cubic feet per minute. During the last year Professor J. H. Long, of the Chicago Medical College, has been making analyses of the hydrant and river water. He finds at State street bridge, which is about half a mile from the mouth of the river, seven parts of free ammonia per 100,000,000 of water, and sixty of albuminoid ammonia; at Polk street, about a mile further from the lake, on the south branch, seventy parts of free ammonia and fifty-two of albuminoid; at the pumping works two hundred and sixty parts per 100,000,000 of free ammonia, and one hundred of albuminoid. At the pumping works on the north branch there were two hundred and forty parts of free ammonia, and eighty-four of albuminoid. Professor Long says: "It is from this source that the lake receives its greatest contamination, for the pumps throw through the conduit into the lake of this vile stuff 16,000 cubic feet per minute. When the wind is favorable a dirty current can be seen floating from the outlet of the conduit toward the crib"¹ from which our drinking water is obtained. That this contaminates our water can be readily seen from the following figures. "During the week past daily tests show amounts of free ammonia ranging between two and eight parts per hundred million, and albuminoid between ten and sixteen parts per hundred million. The microscope reveals the presence of bacteria." Chemists usually consider three parts of free ammonia and five parts of albuminoid per hundred million of water as limits beyond which nitrogenous matter should not go. When the river is flooded in the spring after a general thaw, similar contamination is evident. Professor Long found a year ago in March, both free and albuminoid ammonia. "The amounts decreased from six to eight parts respectively per hundred million the 1st, to one and five per hundred million the 15th. However, in a few days the album-

¹Chicago Tribune, August 3, 1884.

inoid ammonia increased again, and remained nearly double the above amount for a month. This year something similar was observed, and at both times the microscope showed not a few bacteria. The water tested was obtained from a hydrant in the laboratory of the Chicago Medical College on Twenty-sixth street."

If all our river water could be pumped away from the lake, it is evident that our hydrant water could be kept pure. This can only be accomplished, however, by keeping the pumps in action all the year round, and by ceasing to empty the north branch into the lake. The question then arises, how can the water of this portion of the river be disposed of? Perhaps the most economical and best way would be to irrigate the land near the present conduit. Immediately north of it are many of the truck gardens that supply the city with vegetables. It has been found abroad that this is both the most economical and most healthful way of disposing of sewerage water. The method of purification by land irrigation has, however, been but little tried in this country. Pullman, a suburb of this city, furnishes a good illustration of this system. The hydrant water should, however, at all hazards be kept uncontaminated.

PNEUMOTOMY.—With a view to ascertaining what conditions justify this operation, it may be well to recall some of the cases reported of late, although almost every medical journal of the past few weeks has mentioned them, and the particulars may be fresh in the minds of our readers. It is superfluous to repeat any portion of Professor Fenger's paper which appeared in this JOURNAL of the 19th ult., since its facts are accessible, if not well remembered. At the time of its presentation before the State Medical Society, Dr. Fenger's was the second successful case to date. But, at a May meeting of the Royal Medical and Chirurgical Society of London, Dr. Cayley and Mr. Pearce Gould detailed a case of acute circumscribed gangrene of the lung in a girl of twelve years in which the latter gentleman operated the 16th of last February, with recovery. Although not reported until after Dr. Fenger's, it antedated it by two months. Both surgeons were ignorant of the other's proceeding and employed different methods of operating. Mr. Gould punctured with a large trocar and canula, and inserted the drainage-tube through the latter. The result of both operations was the same, and justifies the procedure in this class of cases. At the same meeting reports were made of this treatment in pulmonary cavities; some, that proved to be bronchiectatic, and some,

tubercular. In all marked amelioration of symptoms followed, but no recoveries.

In the *Lancet* of July 5, Mr. Teale, of Leeds, published an instructive case of "Abscess of Lung Cured by Incision and Drainage." This was in March, 1881. The convalescence dragged along for months, but recovery was so complete that when seen last June, the patient was "not conscious of being in other than the most perfect health, is actively at work in his profession every day, and has no discomfort or shortness of breathing during ordinary exertion."

The opening into and drainage of pulmonary abscess would therefore appear to be justified in certain cases.

It only remains to consider the propriety of paracentesis and drainage of pulmonary cavities, and the method to be employed.

It is unfortunate we have not access to the full text of Dr. Biss's paper, since it discussed the drainage of "Pus-Secreting Basic Cavities of Lung," and gave his reasons for dividing them into three classes:

"(1) Those in which paracentesis is imperatively called for; (2) those in which it is unjustifiable; (3) those in which it is a question of special difficulty whether it should be performed or not." The first class would include cases, we think, in which surgical aid is demanded by the gravity of the constitutional symptoms, due to profuse secretion of pus which is ineffectually expectorated and is contaminating the system by its absorption. It also presupposes the demonstration and exact location of a cavity.

The reverse of these conditions would constitute the second, while in the third, many considerations might make the question of operation difficult: The existence and location of a cavity might be doubtful, its size and the amount of expectoration, insignificant, though attended with profound general disturbance; the patient's previous history, bad; or bacilli might be found in the sputum, rendering the chance of ultimate recovery slight, etc., etc. In certain instances the mere amelioration of symptoms and prolongation of life might recommend the treatment. If the surgeon thought there was reasonable prospect of cure by granulation of the walls and a cessation of the unhealthy secretions, or still better of the obliteration of the cavity, as sometimes occurs in spontaneous recovery of circumscribed pulmonary gangrene, no one could well question the propriety of his opening it up and draining off its contents.

Although death occurred in Dr. Biss's case, he did not consider it caused, though hastened by the operation, (since, "the symptoms were considerably, but not wholly relieved,") but by cerebral abscess.

Let us now consider cavities of tuberculous origin. In the cases cited the introduction of the drainage tube was attended with evident abatement of the cough and expectoration, as might be looked for; the fever was also lessened, the appetite improved and strength was gained. None of the patients remained under observation long after the operation, but of course a cure was out of the question. It is improbable that tuberculous walls would heal, and if they should do so, would the progress of the constitutional affection be stayed? It would be curing a manifestation, not the disease itself. Gangrene and abscess are local diseases, and as such benefited by the operation. The drainage of tubercular *vomicæ* is but palliative, yet the surgeon must decide if the gain would warrant his interference.

The shock of pneumotomy does not appear to be very severe. At least the patients seem to have rallied from it without great difficulty.

Irrigation in addition to drainage is desirable, if it does not cause too distressing cough. However, in this regard each case appears to be a law unto itself.

Adhesion of the *pleuræ* at the point of puncture is a desirable, though not an essential condition, to the success of the operation. The existence of adhesions is often impossible of previous determination. Yet this fact should not deter the operation, since no evil results have followed where adhesions did not exist.

Fenger exsects a portion of rib, and leaving *in situ* as a director the needle of the hypodermic syringe, used in exploring, cuts along this with the galvanocautery. The English Surgeons appear to prefer to puncture with a large trocar and canula. This seems objectionable for two reasons:

- (1) There is greater danger of hæmorrhage.
- (2) It is not always easy to penetrate the cavity at the first thrust, and it would be bad to repeat it with so large a trocar as is recommended.

Those among us who are conservative in their endorsement of this operation, except in gangrene and abscess, are not without reason. The method is new, and further experience may develop objections now overlooked in the ardor of enthusiasm. Time tempers enthusiasm and modifies the judgment.

AMERICAN PUBLIC HEALTH ASSOCIATION.—The Twelfth Annual Meeting of this important organization is to be held on Tuesday, Wednesday, Thursday and Friday, October 14-17, 1884, at St. Louis, Mo. The officers and executive committee are actively engaged in making all needed arrangements for a large and useful session of the Association. Special committees composed of active and eminent sanitarians

are expected to report on the Management of Epidemics; on Vital Statistics; on Compulsory Vaccination; on School Hygiene; on Cattle Disease; and on Necrology. There will also be papers and discussions on many other subjects. We trust there will be a large attendance and a profitable meeting. The present active officers are: President, Dr. Albert L. Gihon, U. S. N., Washington, D. C.; Secretary, Dr. Irving A. Watson, Concord, N. H.; Treasurer, Dr. J. Berrien Lindsley, Nashville, Tenn.

PACIFIC MEDICAL AND SURGICAL JOURNAL.—We have received a circular announcing that the *Western Lancet*, of San Francisco, heretofore edited and published by Dr. Whitwell, has been united with its senior contemporary, the *Pacific Medical and Surgical Journal*.

The united journal is to be under the editorial charge of Dr. Gibbons, Sr., and Dr. Whitwell. The former is one of the pioneers of the profession on the Pacific coast, and has ably edited the *Pacific Journal* for more than twenty years. The latter has also given evidence of commendable industry and editorial ability. The new arrangement gives assurance that the profession on the Pacific coast will have one journal worthy of their cordial support, instead of two with a divided patronage insufficient for either.

EARTHQUAKE.—A very decided shock of an earthquake was felt throughout the greater part of the Eastern and Middle States of our country on Sunday, August 10, at 2:10 P. M. In New York City, the motion of the buildings was sufficient to cause the inmates to rush into the streets in great fright. The motion, accompanied by a rumbling sound, continued from two to five seconds. It was felt from Boston to the western part of Pennsylvania, and south as far as Baltimore and Washington. No serious damage was done to buildings anywhere.

CHOLERA.—The epidemic cholera continues to spread slowly in the south of France. It is moderately prevalent in the Provinces of Turin and Genoa, and in several towns in other parts of Italy. A dispatch from London Aug. 11, says that cholera is prevailing at Maufragne near Valence, and at Beziers, with much violence.

YELLOW FEVER.—On the 11th inst. the British ship *Deerfield*, from Havana, was anchored off the mouth of the Mississippi river below New Orleans with yellow fever on board. The captain was warned not to enter the river, but to take his vessel and cargo to Ship-Island for sanitation.

DR. ERASMUS WILSON, OF LONDON.—The death of this eminent physician and author was announced in the secular papers of the 10th inst.

SOCIETY PROCEEDINGS.

MASSACHUSETTS MEDICAL SOCIETY.—PROCEEDINGS OF THE SUFFOLK DISTRICT MEDICAL SOCIETY.—ADJOURNED SPECIAL MEETING.

Section for Clinical Medicine, Pathology, and Hygiene.

ALBERT N. BLODGETT, M.D., SECRETARY.

(Continued.)

Mr. Desmond FitzGerald, C. E., said that the improved system of sewerage for the city of Boston was so designed that if it should ever be found desirable to utilize the sewerage, it could be done, but that in the present experience of dealing with as large a quantity of refuse water as that now supplied by Boston, and considering its highly diluted state, it would be a great waste of money to attempt any scheme of utilization. In regard to inland towns situated on the borders of water-sheds used for sources of water supply, the case was, however, far different. Here very small amounts of sewage had to be dealt with, and there was little doubt in his mind that some scheme either of filtration or irrigation could be successfully applied. The speaker did not intend to use the word success in a pecuniary, but in a sanitary sense.

Mr. FitzGerald proceeded to describe the actual condition at the present time of the several sources of supply of the city of Boston, and of his attempts to preserve the purity of the same. He showed that the time had now arrived when some principle of action must be assumed. Either the brooks must be given up to the towns for common sewers or the towns must be made to take care of their sewerage in a proper manner.

The speaker went on to show that the brooks are now used for drainage only by those people who happened to own land on the margins, while the neighbors immediately adjoining have to provide for their sewage by emptying their cesspools, etc., and the hardship and injustice of this is not denied. Mr. FitzGerald described the works at Sherborne, which are sub-surface irrigation combined with intermittent downward filtration. He said the works had been very much misrepresented, and that while no filtration system removed the chlorine, yet the effluent water was clear and inoffensive to the eye or smell, and practically the filthy condition of the sewage is very materially improved. The speaker agreed with the statements made by Mr. Ernest W. Bowditch at the last meeting, that no cast-iron rule could be made to suit all cases, but that as the circumstances and situation of every town were different, so a study would have to be made of each case and that system adopted which best suited its peculiarities.

Dr. John G. Blake remarked that, looking at the subject from the health stand-point alone, it was becoming every day more necessary that some solution of the sewage question must be attempted if the health of communities as affected by their water supply was to be considered. What is wanted to

hasten the solution of the subject is a law compelling towns bordering on rivers, ponds, and lakes to make some other disposition of their drainage than to allow it to run into these as receptacles. Up to the present time it has been impossible to convict offenders, but during the past winter a law, more stringent in character and free from the defects in previously existing laws, was passed, and under it, action to punish offenders will soon be commenced and pushed vigorously. From what had been said on the subject Dr. Blake is inclined to think that irrigation might prove itself very well adapted for small country communities without any regular system of drainage. The question of profit might well be left for later discussion, and the only point deserving consideration was the disposal of their sewage at the least expense and in such manner as to prevent its becoming a source of injury to themselves and others. Inasmuch as eighty cities and towns are moving to supply themselves with water, the importance of this subject had become very much magnified, and action looking to a remedy must soon be taken.

Dr. Barnes, in closing, said: If the theories advanced in opposition to the employment of irrigation and agriculture for the epuration of sewerage had not been used in Europe, and finally overcome by actual experience, one would hardly feel like continuing to advocate this system for Massachusetts. My enthusiasm, however, does not carry me so far as to suggest even a possibility of the abandonment of Boston's system of intercepting sewerage, notwithstanding the probability of its polluting the lower harbor and producing an unsanitary condition similar to that of the upper harbor, and annoyance to the people living on the south shore, for before this condition is reached it may fairly be anticipated that irrigation and agriculture will have proved here, as in Europe, an economical and practical method of epuration. The sewer can then be extended to the main land and discharged on the soil. "It will not be possible, however, to connect any territory adjacent to Boston with this system without constructing an additional tunnel under Dorchester Bay." This is the language of one of Boston's officials a few weeks since before a committee of the Legislature. Filtration has in numerous instances in Europe, accomplished a complete clarification of sewage, and yet the analyses show the effluent water to contain from one-half to six-sevenths of the original amount of polluting matter. Col. Waring's system of filtration at the Women's Prison accomplishes all that is possible, and yet the analyses show the result to be far from satisfactory. Pasteur and Shloesing, with others, sign a report to the Parisian government in which is stated, "the system of epuration by soil is the only one yet demonstrated to be a success. The discharge should be intermittent, and with methodical rotation, and the doses should be determined by analyses of the effluent water."

At Dantzic is encountered a mean winter temperature about that of our own. Irrigation is continued throughout the year with quite as much success in epuration in winter as in summer, and at all times without offense.

The "winter basins" at Breslau are not a part of the system advocated, as they involve the stagnation of sewage.

"The rosy coloring" of the Gennevilliers farms was not my own painting, but the translation of a report by a commission appointed by the city government of Paris, to whom, it seems to me, ought to be accorded the credit of knowing the facts, particularly as the report was unanimously signed. These gentlemen say "the increase in valuation and population at Gennevilliers is due to farmers coming from other parts of France to share in the general prosperity." Durand-Claye says "the population of Gennevilliers has increased thirty-four per cent. in five years by the arrival of numerous cultivators." M. Joly says of the Gennevilliers farms: "The question, scientific and practical, is absolutely solved." And Dr. Loiseau, at the Geneva Congress, in 1862, said "the benefits derived from these farms are indisputable from every point of view."

I was amazed at the statement that no person knew the cost of the Gennevilliers farms, as I have in my library an official document of Paris pretending to give every item of expense from the first experiment at Clichy, in 1866 and 1868, down to 1881, including lawsuits and large indemnities paid for an unfortunate experiment.

In regard to the city of Pullman making arrangements to pump the sewage into the lake I have the following letter from the superintendent of the farm:—

RIVERDALE, COOK COUNTY, ILL., *May 9, 1884.*

DEAR SIR,—If any such arrangements as you speak of in yours of 6th inst. are being made, I have no knowledge of the fact. The sewage is thoroughly purified by filtration, creating neither offensive odor nor nuisance of any kind.

The farm, last year, paid over six per cent. profit on the money invested (\$80,000), and we hope this year to do even better. Consequently there exists no necessity for any such change as you speak of.

Very respectfully, E. T. MARTIN, *Superintendent.*

HENRY J. BARNES, M.D., BOSTON, MASS.

It should be mentioned here that downward intermittent filtration is a valuable auxiliary to sewage farming. I. Bailey Denton has written considerable upon this branch of the subject. I regret not knowing the history of the Pullman farm, as I should like to pay a proper tribute to the pioneer of this system in America.

The unprofitable results of sewage farming have been dwelt on by most of the opponents of the system, forgetting that it is a question of sanitation and not of making money; and if raising vegetables contributes in any degree to lessening expenses, it takes precedence, in a financial point of view, of all others, as they make no return for the original outlay, except the almost universal offense they create.¹

It has been a long and costly struggle to demonstrate the fact that sewage can be epurated by irrigation and agriculture. Every conceivable danger has

been predicted. And many are the unfortunate and disastrous experiments which can be cited as swelling the cost above the possibility of many of the farms earning interest on the plant. To obtain an act of Parliament authorizing the establishment of a sewage farm, often requires the expenditure of £10,000. Litigation and land damages, another large amount, for land is very dear in England. The heavy clay soil demands a large expenditure for drainage. But notwithstanding these obstacles the number of farms has rapidly increased, until now there are at least two hundred.

The Royal Commissions recommend the enactment of a general law authorizing farms of this character.

In 1876 Messrs. Chesbrough, Lane, and Dr. Folsom, Commissioners, reporting on the sewerage of Boston, say "the Edinburgh farms are profitable." One of the commissions appointed by the Parisian government declares the sewage farms at Gennevilliers profitable, and uses this as one of the arguments in support of their recommendation to the city to purchase the State lands in the forest of St. Germain. The owner of the farm at Leamington (which, by the way, has not been leveled), as well as the superintendent of the farm, claim a good profit after paying the city \$2.250 per year for delivering 1,000,000 gallons each day at the highest point of the farm.

Mr. Aird could not have lost a large amount of money in his contract to take the sewage of Dantzic, for some years later he made a similar contract with the city of Breslau. But it ought not to be required of the friends of this system to show profit until at least one system is devised capable of competition with this in producing satisfactory epuration.

(*To be continued.*)

FOREIGN CORRESPONDENCE.

LONDON LETTER.

FOR THE JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION.

LONDON, July, 1884.

Dr. Morell Mackenzie, of throat celebrity, has published a pamphlet on the subject of hay fever. The information is exhaustive. Hay fever, it seems, like influenza and cholera, did not occur in Europe in ancient times. Bostock, in 1819, first described it; Elliotson did so in 1831, and after him Phœbus, of Giessen. Helmholtz gave his views in 1869, and he was followed by many others. Dr. Morell Mackenzie considers the pollen of certain grasses to be the exciting cause. Dr. Mackenzie differs from the great Helmholtz in the importance which he assigns to quinine. He recommends with the utmost confidence, valerinate of zinc in combination with assafoetida in pills of one grain of valerinate of zinc and two grains of compound assafoetida pill, doubling the dose at the end of ten days or a fortnight. He also alludes to tincture of benzoin in hay asthma, and recommends an inhalation of benzoin, together with an in-

¹ It would hardly seem necessary to affirm before a scientific body of men that clarification is not purification, or that no system of epuration of sewage is satisfactory, which, by analysis, shows quite as much pollution in the effluent as in the influent water. (See analysis of the sewage of the Women's Prison.) As to the average rain-fall of Great Britain, the figures quoted were obtained in the office of the United States Signal Service, and from Professor Niles. But as it is more a question of average humidity which determines the evaporating power, a few inches more or less of rain-fall per year is of little consequence.

sufflation for nose of powdered $\frac{1}{16}$ of a grain of morphia and one grain of bismuth.

News has just been received of the death of Dr. Hunter, of missionary fame. He was the first medical missionary to China of the Irish Presbyterian Church. He died on board steamer returning home. Death resulted from consumption.

Another new and important application of salicylic acid has come to light in the medical world. Dr. Ogilvie, of the Aberdeen Royal Infirmary, having lately had a patient present himself suffering from a peculiar affection of the dorsum of the left foot. The whole of the anterior half of the foot was brown, rough and warty-looking, in fact, not unlike the hide of a hippopotamus. On attempting to detach a small portion, bleeding followed. The disease had existed for two months, and was spreading. Having procured some of Beiersdorf's salicylic plaster, to which Dr. Thin directed special attention at a late meeting of the London Clinical Society as used by Dr. Unna, of Hamburg, in the treatment of cases of thickened epithelium, a certain quantity of the plaster being cut into strips, the affected part of the foot was accurately strapped with it. The dressing was left untouched for three weeks, and on removing it the warty layer came off with the plaster, and a fine, soft, healthy skin was found covering the parts previously diseased. At some points the skin was covered with a thick layer of white, softened epithelial matter, resulting from the peculiar solvent effect exerted by salicylic acid on the epidermic tissues. One or two small warty portions about the roots of the toes had not been covered with the plaster. An attempt to scrape off this warty tissue, first by means of the finger nail, and then by a blunt lancet, was attended by bleeding. To these parts fresh strips of salicylic plaster were applied, and when in ten days they were removed, the skin underneath presented a normal appearance. The results so far have been so satisfactory that Dr. Ogilvie is going to give this novel mode of treatment an extended and careful trial, as there appears to be a wide field of useful application for so simple and efficacious a method for the removal of morbid conditions of the skin. In due course the profession may expect some interesting details of the cases in which the new plaster is employed.

A case has been reported in which a papilloma situated on the sole of the foot was cured by applying to the tumor a Chanteaud granule of salicylic acid by means of a few strips of plaster. The perspiration of the foot dissolved the granule. After this method had been carried out some 20 times the foot was well.

The fourth Masonic lodge founded on the principles of total abstinence, has just been consecrated in London, Dr. W. B. Richardson being Worshipful Master. Amongst the officers are Dr. Beauthwaite, Dr. Quintin Hogg and Dr. N. Kerr. In response to the toast of his health, the well-known sanitary reformer said that if the great principles of Freemasonry were to be carried out to their fullest extent, universal peace, permanent progress, and the brotherhood of humanity, it must be by the adoption of the principles they professed.

The Home Hospital Association have subscribed an additional £10,000 for the purpose of acquiring the adjoining premises of their Fitzroy Hospital, Fitzroy Square, and erecting there and furnishing buildings which will double the accommodation of that flourishing institution. The Home Hospital movement originated in a letter written to the "*Standard*," by M. H. C. Burdett, on April 4, 1877, in which he advocated the formation of an association for the purpose of founding hospitals and convalescent institutions, which should be replete with every possible comfort and provision for the privacy and proper treatment of well-to-do patients, and to which admission should be by payment alone. In consequence of the publicity thus obtained, articles in support of the movement were published in the medical and other newspapers. The Association provides hospital treatment, skilled nursing, and other accommodation, for the benefit of all classes who can afford to pay for such advantages when attacked by illness.

The city Commissioners of Sewers, by the courtesy of Sir Henry Thompson, Sir Spencer Wells, and other members of the Cremation Society of England, have made a visit to the Society's Crematorium at Woking and observed the cremation of a horse. The committee thought it was inexpedient to erect any apparatus for the cremation of the dead, until that mode of disposal has been regulated by Parliament. The bill which was introduced into the House of Commons, with a view to regulate the proceedings in cremation of the dead, has for the present been rejected by a small majority.

At a conference held at the International Health Exhibition, Dr. W. H. Horfield read a paper on "How Infectious Diseases are Caught." He thought the atmosphere was the most universal medium of communication, though some poisons were more readily conveyed in this manner than others. Poisons of several diseases might be conveyed by means of clothing, and laundries were often the agencies of dissemination. An instance was given where chicken-pox had been communicated by means of letters. Drinking water was a most important vehicle for the conveyance of enteric fever, with cholera and dysentery in hot climates, and diphtheria might be spread in this way. Some cases were also given where flies must have conveyed the poison of infectious diseases.

Prince Ferdinand, of Bavaria, brother-in-law to the Duke of Genoa, having published a work with the title "The Anatomy of the Tongue and Studies in Comparative Anatomy," has just received from the University of Munich the honorary degree of Doctor of Medicine.

Geologists of eminence report that within a short time of the shock of earthquake, which in the spring devastated a part of the county of Essex, the level of the water in the wells rose five feet above the highest level ever known. On the Sunday after the shock the water had risen to eight feet, and it has since remained at a rise of seven feet.

NECROLOGY.

FREEMAN, WILLIAM, M.D., the subject of this notice, was born near Lockport, in the State of New York, in 1809, where he received his literary and professional education, and graduated in the Geneva Medical College in 1834. After graduating, he practiced with his preceptor for four years, and then came to the West and located in Hamilton, Butler Co., Ohio. Here he was married, and practiced his profession until 1847. He then removed to Camden, Jay Co., Indiana, where he continued in active practice until the day of his death, April 17, 1883, being 75 years old lacking 11 days.

Dr. Freeman served three years in the army during the late war, one as Assistant-Surgeon of the 53d Ind. Vol. Inf., and two years as Surgeon of the 7th Ind. Cavalry, under Gen. J. P. C. Shanks. He became a member of the Grant County Medical Society on the 8th of June, 1850, many years before there was any society organized in his own county. He was one of the organizing members of the 11th Congressional District Medical Society, which passed appropriate resolutions of respect for his memory, an active member of the Indiana State Medical Society, and at the time of his death President of his own county society.

Dr. Freeman was a diligent student and an active, energetic practitioner. By keeping up with the advancing improvements of the day, he always maintained a prominent position in his profession.

He was intolerant of sham devices and false pretenses as substitutes for the merit of real knowledge and scientific attainment in the profession.

In his death the profession lost an earnest member, who was ever ready to give his aid and influence to any measures calculated to promote the usefulness of his calling, and the community the services of a true man and an honorable physician.

His death was caused by an encysted tumor of the brain. It was sudden and unlooked for at the time. He had occasionally suffered from vertigo and cerebral symptoms for some 18 months prior to the fatal termination, but was able to attend to the duties of his profession up to the day of his death. Material for this notice was furnished by a son of the deceased, B. R. Freeman, M.D.

L.

MISCELLANEOUS.

MEMORIAL TO THE LATE DR. AMBLER, U. S. NAVY.

The officers of the Medical Corps of the United States Navy some months ago determined to erect an appropriate memorial to their late associate, Dr. Ambler, and after a conference of views it was decided to commemorate him by a granite monument on the lawn in front of the U. S. Naval Hospital at Norfolk, Virginia, and a bronze tablet to be placed in Leeds church, near his home, at Amblerville, Fauquier county, Va., where he has been buried.

The committee to whom this work was intrusted, and of which Dr. Edward Shippen, of the U. S.

Naval Hospital at Philadelphia, is chairman, have just completed this tablet, which will soon be placed in the church. It bears the following inscription:

JAMES MARKHAM AMBLER,

PASSED ASSISTANT SURGEON UNITED STATES NAVY.

Died on the banks of the Lena River during the memorable retreat of the ship's company of the U. S. Arctic steamer Jeannette, in the year

1881.

His sense of duty was stronger than his love of life.

In memory of his noble example and heroic death this Tablet is erected by the Medical Officers of the United States Navy.

OFFICIAL NOTICE.

ANNUAL DUES from members of the Association—*Five Dollars* per annum—are payable directly to the Treasurer. Such payment entitles them to receive the JOURNAL of the Association for one year.

SUBSCRIPTIONS TO THE JOURNAL from those who are not members should be forwarded to the office of publication, Chicago.

BACK VOLUMES OF THE TRANSACTIONS may be procured, at reduced rates, by addressing the Treasurer.

THE INDEX to the 33 Volumes of Transactions will be forwarded, postpaid, on receipt of *One Dollar* by the Treasurer.

According to a resolution passed May 9, 1884, at the Washington meeting, continuous payment of Annual Dues is required, to retain permanent membership.

RICHARD J. DUNGLISON, M.D.,

Treasurer.

Lock Box 1274, Philadelphia, Pa.

LIST OF OFFICIAL CHANGES IN THE MEDICAL CORPS OF THE NAVY, FOR THE WEEK ENDING AUGUST 9, 1884.

Assistant Surgeon J. S. Sayre, ordered to U. S. S. "Independence."

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT UNITED STATES ARMY, FROM AUGUST 2, 1884, TO AUGUST 8, 1884.

Woodward, Jos. J., Major and Surgeon, sick leave of absence extended six months. (Par. 9, S. O. 178, A. G. O., July 31, 1884.)

Gibson, J. R., Major and Surgeon, granted leave of absence for 1 month and 16 days. (S. O. 36, Hdqrs. Div. of the Atlantic, August 4, 1884.)

Heizmann, C. L., Captain and Assistant Surgeon, relieved from duty at Columbus Bks., Ohio, and ordered for duty in Dept. of the East. (Par. 2, S. O. 186, A. G. O., August 2, 1884.)

McCreery, Geo., 1st Lieutenant and Assistant Surgeon, leave of absence extended two months. (Par. 4, S. O. 180, A. G. O., August 2, 1884.)

Taylor, A. W., 1st Lieutenant and Assistant Surgeon, ordered for temporary duty at Fort Riley, Kans. (Par. 1, S. O., 153, Hdqrs. Dept. of the Mo., July 29, 1884.)

Hopkins, W. E., 1st Lieutenant and Assistant Surgeon, granted 1 month leave of absence, with permission to apply for 1 month's extension. (Par. 1, S. O. 67, Hdqrs. D. of Arizona, August 1, 1884.)

ON BRANCHIAL CYSTS OF THE NECK.

BY N. SENN, M.D., MILWAUKEE, WIS.

Read in the Section on Surgery and Anatomy of the American Medical Association, May, 1884.

The differential diagnosis and operative treatment of tumors of the neck, are subjects which belong to the most imperfect and unsatisfactory topics in surgery. The great difficulties which are often encountered in the diagnosis of cervical tumors, and the importance of the anatomical structures which are involved in all operative procedures for their removal, are well known and appreciated by all who can speak from personal experience. One of the most important, and, at the same time, one of the darkest chapters treating of tumors in this region, relates to cystic tumors, and more particularly that variety which originates from congenital defects of development, the matrix being composed of foetal epiblastic or hypoblastic tissue, which remains in its embryonal state for an indefinite time, and later, by proliferation of its epithelial elements, gives rise to a distinct and characteristic type of cystic tumors. These tumors have been variously designated as branchial cysts (Roser), dermoid cysts of the sheath of the internal jugular vein (Langenbeck), deep-seated atheromatous tumors (Schede), tumors of the branchial clefts (Virchow), hydrocele colli congenita (Mannoir), hygroma colli (Luschka), atheromatous cysts of lymphatic glands (Luecke), in accordance with the nature of the contents of the tumor, or the peculiar etiological views entertained by different authors. It appears to me, however, that "branchial cysts" is the most appropriate term, as it expresses at once both the location and the character of the tumor.

EMBRYOLOGICAL AND ANATOMICAL REMARKS.

Toward the end of the first month of foetal life, we see under the frontal process, open in front and bounded on the sides by four plates, the pharyngeal cavity. The upper pair of plates constitute the first branchial arch. The next three pairs of plates make up the second, third, and fourth branchial arches, which decrease in size from above downward, so that their median interspaces in front are narrow above and wider lower down. Between each pair of branchial arches on each side remains a transverse cleft,

the branchial clefts, which unite during early foetal life, with the exception of the first one, from which the external auditory canal, the cavity of the tympanum (middle ear) and the Eustachian tube are developed. The neck is thus built up of continuous lateral walls. From the second branchial arch are developed the styloid process, the stylo-hyoid ligament, the lesser cornua of the hyoid bone; the third arch forms the large horns and the body of this bone; the fourth arch assists in forming the soft tissues of the neck. The larynx, trachea, and adjacent glands are developed from other centres of foetal growth. The primary origin of these tumors necessarily must correspond to the location of one of these branchial clefts, and clinical experience has demonstrated that they are most frequently found in the region of the second and third branchial clefts, in the vicinity of the larynx, pharynx, and in intimate relation with the sheath of the large vessels of the neck, in contradistinction to dermoid cysts about the orbits and in the scalp, which are more superficially located (Langenbeck). In the case of a young lady, Langenbeck observed a cyst situated on the left side of the epiglottis and pharynx, which occupied one-half of the floor of the mouth, and which projected from underneath the chin on that side in the shape of a smooth tumor of the size of a fist. Respiration, deglutition, and motion of the tongue were greatly impeded. The cyst contained eight ounces of atheromatous matter. The same author states that he has frequently found these tumors attached to the greater horn of the hyoid bone or to the thyro-hyoid ligaments, localities which plainly indicate that they originated from remnants of former branchial clefts.

We shall have frequent occasion to allude to the intimate connection of these tumors with the sheath of the large vessels of the neck, consequently it is very important to study their anatomical relations to these important structures. The jugular vein is surrounded throughout its whole course in the neck by a distinct and separate sheath of areolar tissue, which, on the outer side of the artery, penetrates into the deep tissues of the neck, thus completely separating the two vessels. The jugular, enclosed in its sheath, may be easily drawn over the artery toward the median line without producing any change of location of the artery. The vein being in front of the artery, and covering half of the lumen of the latter, it can be readily understood that when the vein is drawn forward with its sheath, it can be injured while the artery is not exposed to the same danger. Branchial cysts of the second and third clefts are always ob-

served in the sheath of the large cervical vessels, usually in the carotid triangle above the omo-hyoid muscle. They appear to occur more frequently on the left side of the neck. Their shape is invariably round or oval, with a smooth surface. The contents of these cysts being either fluid or semi-fluid, fluctuation can be felt, more particularly if the tumor is palpated between two fingers from the pharynx or the floor of the mouth and the external surface. Only lateral motion of the tumor is possible, on account of its peculiar attachments to the deep tissues of the neck. If the tumor is only of moderate size, the pulsations of the carotid artery can be felt on its inner margin. If it is large, it overlaps the artery, when the pulsations of the vessel are communicated to the tumor. Smaller tumors can be made to pulsate, by bending the head backward and in a direction opposite to the tumor.

HISTORICAL NOTES.

Nearly forty years ago Roser of Marburg made the statement that many of the so-called ranulas about the base of the tongue, the mucoïd and dermoid cysts of the upper cervical region, are due to imperfect closure of one of the branchial tracts. All of these tumors he included in one group under the name of branchial cysts. He described three distinct conditions which may result from entire absence or imperfect obliteration of any one of the branchial clefts.

1. Branchial fistula in case the entire tract remains patent.

2. Cystic fistula in case only one extremity of the cleft is obliterated while the other communicates with the pharynx or the cutaneous surface.

3. Branchial cysts in the event the tract is closed at both ends while between them it remains open, and by proliferation from the inner surface produces an accumulation—the contents of the cyst.

Although these tumors are by no means common, a sufficient number of well authenticated cases have been placed on record which remove all doubt as to the etiological relations which exist between imperfectly obliterated branchial clefts, the serous, dermoid, and the so-called deep-seated atheromatous tumors, of congenital origin and located in the regions formed by the branchial clefts. These tumors have since been made a special object of study by B. von Langenbeck, Luecke, Gurlt, Virchow, Schede, Esmarch and Heusinger.

CLASSIFICATION OF BRANCHIAL CYSTS.

Branchial cysts should be classified according to their contents. The cyst walls being lined with epithelium, the only histological element in the contents are epithelia. In most instances the epithelia lining the cysts belong to the tessellated variety, but Rehn discovered in a blind congenital fistula ending near the mucous membrane of the pharynx, ciliated epithelium; and Neumann found cylindrical and pavement epithelium in two cystic tumors of the neck, one of which was congenital, while the other was developed in later years. The presence of ciliated epithelium may be explained by assuming its origin to have been in the upper part of the cleft, the fornix pharyngis, where these fistulæ oftentimes end, and where ciliated

epithelium normally exists. The lower end was probably lined with flat epithelium.¹ The physical and chemical properties of the cyst contents will depend largely on the amount and degree of retrograde transformation of the epithelial proliferation. In making the character of the cyst contents a basis for classification it is, however, important to remember that like in ordinary retention cysts, the contents of a branchial cyst are liable to undergo changes depending on the retrograde changes of the epithelial product, hæmorrhage and other transudations into the sac, or the occurrence of inflammation in the cyst wall itself. It is only during the earliest stage that the specific secretion is found in its purity. In the course of time the original character of the contents of the cyst may be completely lost by retrograde metamorphosis, or the addition of new material. Clinical experience and pathological examinations have shown that these tumors, according to the physical properties of their contents, may be divided into the following four principal varieties:

1. Mucous cysts; 2. Atheromatous cysts; 3. Serous cysts; 4. Hæmato-cysts.

Variable as the contents of these different varieties may be, more uniformity is observed in the structure of the cyst wall. In the primary stage of the affection it consists of a connective tissue capsule with an epithelial lining on its inner surface, and a delicate layer of a loosely connected reticulum of connective tissue (pericystium) which is very vascular and covers the outer surface of the cyst. A high degree of intracystic pressure may cause atrophy of the epithelial lining and thinning of the walls of the sac and, on the other hand, inflammatory proliferation produces great thickening of the cyst walls. While dermoid cysts contain the characteristic secretions of the skin and its appendages, the branchial cysts only contain the products of the epithelial cells because their walls do not contain any hair follicles, sebaceous or sweat glands, as the branchial clefts close before these appendages are formed.

1. *Mucous branchial cysts.* As a primary formation this form of branchial cyst is usually found in the upper branchial clefts. Their origin is attributable to an imperfect closure of the upper portion of the branchial tract, consequently the cyst wall may derive its lining from the mucous membrane of the pharynx, and the retention of the physiological secretion produces a mucous cyst. Many of the so-called ranular cysts about the base of the tongue belong to this variety of tumors. Among the six types of branchial cysts mentioned by Roser, the third variety consists of a cystic formation which extends from under the tongue towards the neck; the sac assumes an hour-glass shape, the constricted portion connecting the cervical with the lingual portion of the cyst. By making alternate pressure over the cyst, the contents may be squeezed from one portion of the cyst into the other. Congenital mucous cysts in the region of the base of the tongue and sides of the larynx in the majority of cases are due to an imperfect closure of the upper portion of one of the branchial tracts.

¹Kœnig, Lehrbuch der spec. Chirurgie. Berlin, 1878. Vol. i, p. 454.

2. *Atheromatous branchial cysts.* This form of branchial cysts has been described by some authors as deep-seated atheromatous cysts of the neck (Schede), and dermoid cysts of the sheath of the large vessels of the neck (Langenbeck). They are usually located in the second and third branchial tracts in the region of the hyoid bone, and intimately connected with the sheath of the large cervical vessels. These cysts contain an atheromatous material resembling the contents of an ordinary retention cyst of the skin, with this difference, however, that they never contain anything which would indicate the presence of hair follicles, as lanuginose hair or sebaceous material, or any of the more complicated products of dermoid cysts. Schede¹ has made a careful microscopical examination of the sac of a deep-seated atheromatous branchial cyst. The specimen was hardened in Müller's fluid. The inner surface of the sac was lined with layers of tessellated epithelium. The deeper layers were composed of oval or spindle-shaped cells with delicate filiform processes which were arranged in a perpendicular direction to the walls of the cyst. The nuclei were either longitudinal and granular or round, completely filling the centres of the cells. If any attempts were made to tear the epithelia from their points of attachment it was observed that the different layers were arranged in such manner as to appear dove-tailed. The superficial layers showed large polygonal cells with distinct nuclei. The portion of the capsule next to the epithelia, consisted of thick concentric layers of thin fibrillated areolar tissue. Occasionally the fibrils were wanting, their space being occupied by a pale homogeneous mass of a granular substance. Outside of this structure the capsule was composed of strong bundles of connective tissue which were arranged in concentric layers, but forming a distinct reticulum. The blood-vessels in the walls of the sac were scanty, small in size, with exceedingly thin walls penetrating as far as the epithelial lining. No trace could be found of hair follicles, sudoriparous, or sebaceous glands.

For the purpose of furnishing a clear clinical picture of this form of branchial cysts I will give a synopsis of a few typical cases.

Langenbeck's case.² The patient was a female 17 years of age. Suffered from enlargement of cervical glands during her 12th year. Two years before the operation a soft swelling was noticed in the region of the left carotid triangle, which soon increased to the size of a hen's egg. A year later the whole neck, but especially the left side, was swollen, and the tonsils at the same time were considerably enlarged. Pains in the neck, and frequent attacks of angina had preceded these symptoms. The usual medicinal treatment in such cases and a visit to Kreuznach improved her general health, but the tumor increased in size, became more prominent, and showed distinct signs of fluctuation. At the time of operation, two years after its appearance, the tumor was oval in shape, and extended from the angle of the jaw down-

wards to a line on a level with the cricoid cartilage. Externally it was not very prominent, but on further examination it was evident that its base was firmly attached to the sheath of the large cervical vessels. The tumor could be felt through the walls of the pharynx, where fluctuation was distinctly felt. The anterior margin of the sterno-cleido-mastoid was somewhat elevated by the outer portion of the tumor, which received a distinct impulse from the underlying artery. The pulsations were felt most distinctly when the head and neck were turned toward the opposite side and in a backward direction. The tumor was punctured and a mass of yellowish semi-solid substance escaped, the solid portions of which were composed of epithelial cells and cholesteroline crystals. The puncture was kept open by a linen tent. Later injections were made into the interior of the cyst of tr. iodinii, and when this produced no effect a concentrated solution of nitrate of silver was tried with no better result. The wound was kept open for a long time, but in spite of all efforts the cavity showed no tendency to close. A year later a seton was passed through the tumor, but without success, for as soon as it was removed the openings closed, and the cyst increased to its former size, causing pain and pressure, necessitating an incision which gave exit to a large quantity of foetid pus. For four months the wound was kept open and iodine injections were again resorted to, but with no better effect than before. Nearly three years from the time the cyst was first noticed it was removed by extirpation. An incision was made along the anterior border of the sterno-cleido-mastoid, extending from the angle of the jaw towards the cricoid cartilage. In consequence of the long-continued inflammation, the cicatricial adhesions between the cyst walls and the surrounding tissues were found very firm, and could only be separated by a tedious and difficult dissection. When an attempt was made to isolate the tumor from the deep structures it was found to be intimately connected with the sheath of the internal jugular vein, so that, on making traction, the vein was elevated from its bed while the artery remained *in situ*. The base of the tumor and the vein appeared to form one coherent mass. The tumor was carefully drawn forward, the sheath of the vein opened and the attachments separated with the handle of the scalpel. The cyst extended upwards close to the jugular foramen and was attached to the styloid process. When the tumor was removed, the parotid gland, the styloid process, the submaxillary gland, and the right wall of the pharynx became visible in the wound. The internal jugular vein, deprived of its sheath, was seen completely isolated throughout the whole length of the wound. The carotid artery enclosed in its sheath lay also exposed in the wound. Hæmorrhage was moderate. Adhesive strips and lint compress constituted the dressing. The patient recovered without any untoward symptoms.

Langenbeck's case.¹ This was again a female, 20 years of age, otherwise in robust health, who consulted von Langenbeck in May, 1855. When nine years of age a tumor appeared on the left side of the

¹ Ueber die tiefen Atherome des Halses. *Archiv f. Klin. Chir.*, vol. xiv, p. 1.

² Beiträge zur chir. Pathologie d. Venen. *Archiv f. Klin. Chir.*, vol. i. page 1.

¹Op. cit., p. 25.

neck, which rapidly increased in size. One year later Dieffenbach made an attempt to extirpate it, but when he discovered that it was adherent to the deep tissues of the neck he desisted from any further attempts to remove it, and contented himself with making an incision into the sac and emptying its contents, which had the appearance of a thin gruel. The cyst refilled and was again reopened by means of the actual cautery, the contents being of the same character as before. The wound was kept open for a number of years, and the cyst discharged continually. Finally the opening closed, and the tumor disappeared almost completely until, in 1854, it again increased in size, and when first seen by Langenbeck, it was as large as a pigeon's egg. It occupied the left side of the neck on a line with the upper border of the thyroid cartilage, and between it and the inner border of the sterno-cleido-mastoid. It was firm, but imparted to the touch an indistinct sense of fluctuation. The cicatrices resulting from previous operative procedures had produced firm adhesions between the sac and the skin. With some difficulty the tumor could be separated from the artery. Its location rendered it probable that it was connected with the sheath of the cervical vessels. As the tumor increased and became more painful, it was extirpated May 10, 1855. The unyielding cicatricial tissue was included in the incision and removed, the fascia of the neck was divided and the inner border of the sterno-cleido-mastoid exposed. It was found extremely difficult to sever the adhesions around the cyst walls, and the sac was ruptured on the inner surface during one of these attempts. The collapsed sac was seized with sharp hooks and drawn over toward the median line of the neck, and while the sterno-mastoid muscle was pushed in an opposite direction the dissection was continued carefully toward the base of the tumor. A broad pedicle connected the cyst with the large cervical vessels. With the index finger the carotid artery was pushed backwards and outwards with a view to keep the jugular vein, which was on the outer side of the artery, at a safe distance. As the pedicle was being divided with the scissors a sudden gush of dark venous blood welled up from the bottom of the wound, which in a moment completely flooded the neck and the operating table. The operator immediately made digital compression above and below the wound, while an assistant made direct compression with a sponge. The hæmorrhage soon ceased and the sponge was carefully removed. A careful inspection of the floor of the wound showed that the jugular vein was completely out of sight, covered by the muscular tissues of the neck, and as the hæmorrhage had ceased, it was not deemed advisable to resort to any severer measures for the purpose of guarding against another attack of hæmorrhage. After removing all coagula the wound was filled with lint, its margins were drawn together with strips of adhesive plaster, over which a compress was applied. An icebag was placed over the seat of operation. The wound healed kindly and the patient made a complete recovery. An examination of the cyst revealed that a piece of the anterior wall of the internal jugular vein, four lines in length, and two and one half lines in width, was attached to its under

surface. Professor A. Luecke, then Langenbeck's assistant, in a paper on "Atheromatous Cysts of the Lymphatic Glands,"¹ makes the following comments on Langenbeck's first case: The attempt to remove the tumor by puncture and subsequent injections of iodine had failed, hence extirpation was resorted to. Traces of the former operative procedures may still be seen in the tumor, and its peculiar structure renders evident why simple puncture and injection proved unavailing. The external appearance of the tumor presents a greater similarity to an hypertrophied lymphatic gland than to an atheromatous or dermoid cyst. It has the same oval shape, and the different processes of areolar tissue that I have observed in cases of lymphatic sarcomata. It is surrounded by a thin capsule of areolar tissue and before removal gave evidence of distinct fluctuation. To differentiate between a tumor of this kind and a suppurating hypertrophied lymphatic gland is, even after removal, extremely difficult if not impossible. Errors in diagnosis are therefore not only possible but often unavoidable, but fortunately they are of no great consequence in respect to the treatment. When an incision in the tumor was made a purulent fluid was discharged, which under the microscope presented the characteristic atheromatous matter.

Gurlt² mentions the great similarity existing between the contents of these tumors and those of ovarian cysts. We see in our case under the microscope, fat-cells, large masses of epithelia either without or with multiple nuclei. Many cells are filled with free molecular fat, others contain fat-cells, and occasionally large nuclei are seen. We also observe the well-known crystals of cholesterin and small prismatic crystals which seem to be some form of inorganic salt, also lime in granular form. He quotes F. Hoppe, who has made a careful chemical examination of the contents of an atheromatous cyst, and has found the following to represent its chemical composition: 1.3953 grammes of atheromatous material contained the following: 0.2225 alcoholic extractive matter, 0.1235 ethereal extractive matter, 0.2005 aqueous extractive matter, 0.8555 insoluble matter. In these different ingredients he found leucin, tyrosin, cholesterin, myelin, palmitin, and stearin. Usually these cysts constitute spherical cavities surrounded by a thin smooth membrane, rarely with thickened walls or wart-like elevations, or fan-shaped protuberances, but in this instance we see cavities of greater or less size embedded in a dense parenchyma of a reddish white color which constitutes the bulk of the tumor. The cavities are distinctly separated from each other, and are not in contact with the external capsule of areolar tissue. Wart-like vegetations cover the cyst wall and protrude from it. Sections through the parenchyma show small spaces separated by areolar tissue and filled with granular matter. The contents of these follicles are lymph corpuscles and amyloid granules. These latter were soluble in glycerine, but remained unaffected by acids and alkalies.

In opposition to the views advanced by Luecke, it

¹Ueber Atheromcysten der Lymphdrüsen. *Archiv f. Klin. Chir.* vol. 1, p. 356.

²Die Cystengeschwülste des Halses. Berlin, 1855, p. 268.

may be stated that the consecutive attacks of inflammation and suppuration so modified the contents and altered the structure of the cyst walls that the primary structures of the tumor was lost. The cyst wall by chronic inflammation became thickened, and the tissue proliferation of the adjacent structures may have invaded the interior of the sac and thus rendered an anatomical diagnosis exceedingly difficult or impossible. The location of the tumors, the clinical history, as well as the age of the patients, render it more than probable that both of Langenbeck's cases were atheromatous branchial cysts.

Schede calls these cysts deep-seated atheromatous cysts of the neck, without reference to their origin from imperfectly closed branchial clefts. I will describe in brief the three cases that came under his observation at Volkmann's clinic.

*Volkmann's case reported by Schede.*¹ The first case was that of a young man 17 years of age, who had always enjoyed perfect health. Two years before the operation the patient noticed a small smooth and round tumor which began to develop on the side and upper portion of the neck close to the anterior margin of the sterno-cleido-mastoid. It was painless, somewhat movable, and soon increased in size so as to give rise to deformity, and difficulty in deglutition. In February, 1870, it had reached the size of a goose-egg, presenting a smooth surface and a round or oval contour. The tumor was punctured at this time with a trocar, when about 30 grms. of a cream-like fluid was removed. The puncture was followed by an injection of tr. iodinii which was again withdrawn after remaining for a few minutes. The microscope showed an abundance of large flat cells in the fluid removed. In a month later the tumor had returned to its former size. A longitudinal incision was now made over the tumor and the cyst extirpated. The adhesions were not firm, and the operation was completed without meeting with any difficulties. The tumor was situated upon the sheath of the large cervical vessels, but was easily separated from them. Posteriorly it extended to a point between the pharynx and trachea. The wound healed promptly and the patient recovered completely.

*Volkmann's second case reported by Schede.*² This was also a young man 15 years of age, who, 18 months previously, noticed a small tumor on the anterior margin and about the middle of the sterno-cleido-mastoid. It increased slowly in size and resisted all ordinary attempts at treatment. When he came under Volkmann's care it had attained the size of a hen's egg. It was painless, oval in shape, with a smooth surface, and presented evidences of fluctuation. The extirpation of the tumor was again done and presented no difficulties whatever, as the attachments were not firm and could be easily separated. Posteriorly it reached as far as the cervical vertebrae, which could be plainly felt after the removal of the cyst. The walls of the sac were very thin and a microscopic examination of the contents revealed the presence of epithelial cells in a state of fatty degeneration.

*Volkmann's third case reported by Schede.*¹ This case was a female, 22 years of age, who, when 11 years old, noticed a small tumor in the left upper cervical region. Irritating applications had induced inflammation, suppuration, and a spontaneous evacuation of a thin sanious pus, whereupon the tumor disappeared. In her 17th year the tumor reappeared in the same place which, in spite of all treatment, increased in size, encroaching somewhat upon the cavity of the mouth. At the time the operation was performed it extended from the mastoid process to the angle of the jaw, being about 2½ inches in length and 1½ inches in breadth. The tumor was painless and movable, moderately tense, and through the mouth fluctuation could be detected. The cyst was removed through an incision parallel with the lower margin of the jaw. The adhesions in front and on the sides of the tumor were slight, but the attachments to the styloid process were firm, and were severed with the finger. The sac was opened and contents evacuated to facilitate the detachment of the cyst from the deep structures beneath; this was done with curved scissors. The tumor was not adherent to the sheath of the large cervical vessels in this case. Like in the preceding cases, the contents were composed largely of epithelial cells. Recovery was prompt and permanent.

The cases reported by Schede furnish an instructive and practical illustration of the fact that the firm adhesions to the sheath of the deep cervical vessels which were observed in Langenbeck's cases are the direct result of prolonged irritation and inflammation in the walls of the sac and the adjacent tissues, and that the removal of these tumors can be accomplished with comparative ease provided such inflammation has not preceded the operation.

*Virchow's case.*² Under the name of auricular teratoma of the neck, Virchow describes a branchial cyst in the person of a seamstress 24 years of age. It was first noticed when the patient was in her 14th year, when it was as large as a filbert. It increased slowly in size, and when first seen by Virchow it had attained the size of a goose-egg. It was located between the angle of the jaw and the mastoid process, and was firmly attached to the sheath of the carotid artery. The cyst was filled with a creamy yellowish fluid which contained free fat and epithelia. The walls were studded with sebaceous follicles, especially on the side toward the carotid artery. The portion attached to the sheath of the vessels contained a plate of cartilage which resembled the cartilage of the ear, hence he designated the tumor as an *auricular* teratoma. Virchow attributed the origin of this and analogous growths, to an imperfect obliteration of one of the branchial clefts. In his classification he includes the cysts which are developed from branchial clefts among the teratoid tumors.

Three cases of atheromatous branchial cysts have come under my own observation.

General health excellent. About a year ago the patient discovered a small tumor on the right side of the neck between the angle of the jaw and the larynx, which slowly increased in size, and after a few months became the seat of an acute inflammation which terminated in suppuration, requiring an incision for the relief of urgent symptoms. The fluid which escaped consisted of pus mixed with a gruelly substance. Prompt relief followed the incision. The inflammatory symptoms subsided and the tumor diminished in size. In a few weeks the opening closed, leaving a small and painless swelling. The same symptoms were repeated about four months subsequently. When the patient came under my observation during the summer of 1883, I found a tumor about the size of a hen's egg located between the angle of the jaw and the larynx, resting directly upon large vessels of the neck, as was evident from the distinct pulsations which it received and which could be seen and felt. The posterior portion was under the sterno-cleido-mastoid. Over its centre was seen the scar which had resulted from the previous incisions. The swelling presented a regular smooth surface and an oval outline with the long diameter parallel to the cervical vessels. (Fig. 1.)

Fig. 1.

It was only slightly movable from side to side and perfectly immovable from above downward, showing that it had a firm point of attachment to the deep tissues of the neck. Fluctuation could be detected on the outer surface and also through the mouth. The original location corresponded to the third branchial cleft. As it had on two different occasions undergone acute inflammatory changes without any benefit resulting from them, the extirpation of the cyst was deemed the only measure which promised a permanent result. The operation was done under antiseptic precautions. A straight incision was made over the tumor parallel to the sterno-cleido-mastoid. The cyst was found firmly adherent to the surrounding tissue as the result of

the antecedent inflammatory infiltrations and required much time and patience in its separation. After isolating it from all attachments on its sides, it was seized with a tenaculum forceps and drawn forward and toward the median line of the neck, while the sterno-cleido-mastoid was held in an opposite direction so as to afford easy access to its base. The attachments here were very firm, and it appeared as though the base of the tumor and the large cervical vessels underneath were imbedded in a mass of cicatricial tissue. Keeping as close to the cyst wall as possible, the dissection was continued very carefully, proceeding mostly with blunt instruments. When nearly one-half of the pedicle was separated in this manner, we were suddenly surprised by a tremendous gush of dark venous blood, which in a second flooded the whole field of operation. It was only too evident that the internal jugular vein had been torn, and, for the purpose of preventing further loss of blood and to guard against instant death by admission of air into the vein, I made firm digital compression above and below the injured vein, while an assistant pushed a sponge into the wound. Hæmorrhage was controlled in this manner, and as soon as I could be relieved by one of my assistants I removed carefully the sponge, and, after locating as nearly as possible the exact seat of bleeding, I seized the vein with some of its adjacent tissues with a stout pair of hæmostatic forceps. I was fortunate enough to grasp the bleeding point at the first attempt, and the hæmorrhage was completely controlled. The tumor was now removed, and by making slight traction on the forceps the vein was drawn forward and a catgut ligature applied without isolating the vessel. I was unable to ascertain the exact size or direction of the wound in the vein, but the ligature arrested the hæmorrhage promptly and permanently. The wound was thoroughly irrigated, and, like in Langenbeck's case, the vein seemed to disappear underneath the deep tissues of the neck. In the wound could be seen the œsophagus, lateral wall of the larynx, carotid artery in its sheath, and the great horn of the hyoid bone. After suturing and draining the wound a graduated compress was applied. For the first 24 hours after the operation the patient suffered from intense headache in the corresponding side, which induced me to believe that the circulation in the vein had been completely interrupted, either by the ligature alone or by the formation of a thrombus at the point of ligation. After the first 24 hours the patient suffered no further inconvenience. The wound healed by primary union and the recovery has been permanent and complete. There is no question but that the adhesions of the cyst with the sheath of the cervical vessels were due to the attacks of acute inflammation which had preceded the operation on two different occasions. A microscopical examination of the contents showed flat epithelial cells, cholesterine crystals, fat granules, and a mass of debris, the product of epithelial degeneration.¹ The cyst wall was composed of connective tissue, thickened and infiltrated with embryonal elements and lined with flat epithelial cells.

CASE II. Mrs. P., æt. 22, American. Family history good, especially in reference to congenital deformities. About a year ago she noticed on the right side of the neck near the angle of the jaw a small deep-seated tumor, which, after attaining the size of a filbert, remained stationary, at times even diminishing somewhat in size. About two months ago it began to increase in size, and became the seat of a feeling of distress and pain. When she presented herself for examination (Dec. 13, 1883), it was about the size of a hen's egg. It is located over the bifurcation of the common carotid artery, pulsates distinctly, and makes pressure against the floor of the mouth and larynx, and reaches from the lower jaw to the upper border of the thyroid gland. Fluctuation is distinct, and can be distinguished through the mouth. The skin over it is natural in

appearance and movable. At the base of the tumor firm attachments fix it to the deep tissues of the neck, which prohibit any motion from above downward, while slight lateral motion is possible. The history of the case, the age of the patient, the location of the tumor in the region of the third branchial cleft, appeared to furnish sufficient evidence to justify me in diagnosing an atheromatous branchial cyst. The patient objected to an operation, and I have not been able to ascertain the subsequent history of the case.

CASE III. *Branchial cyst in the region of the second branchial cleft.* Mary H. æt. 25, German. Her family history is good, especially regarding congenital malformations, as tumors or fistulæ in the cervical region. Patient has always appeared round and full underneath the chin, but during the last four years a tumor has been growing rapidly on the floor of the mouth until, at present, it is considerably larger than a goose egg. The mouth is completely filled by it, the tongue is pressed against the palate, its movements are limited, only the tip of it being visible at the upper border of the tumor, and speech and deglutition are greatly impeded. (Fig. 4.)

Fig. 4.

Small dots in the mouth to represent the openings of Wharton's ducts.

Laterally, the tumor extends to near the angles of the inferior maxillary bone, and downward it overlaps the larynx and upper part of trachea, entirely obliterating the round contour of the upper cervical region. It is painless, and distinctly fluctuating to the touch, presents a smooth surface, and gives rise to no further inconvenience except from its mechanical interference with speech and deglutition. When the patient opens her mouth the apertures of Wharton's ducts are plainly visible on each side of the median line, and by exerting lateral pressure upon the sub-maxillary glands the patient can expel a stream of saliva from them. Previous treatment, as external application of iodine, etc., had had no effect on the growth.

Operation. Desiring to avoid any deformity resulting from an external cicatrix, it was decided to remove the tumor through the mouth. A linear incision was therefore made in the median line, from

above downward, extending from the tip of the tongue to the symphysis of the lower jaw, carefully avoiding the ducts of the salivary glands. When the sac of the tumor was reached, the adhesions existing between it and the surrounding tissues were easily severed with the handle of the scalpel. After freeing about one-half of the tumor in this manner it was found that it would be impossible to remove the tumor in its entirety in this manner, owing to its immense size. The sac was therefore opened and a large quantity of its gruelly contents removed by pressure. The operation then proceeded without any difficulty until the entire cyst was removed. It was now noticed that the cyst was constricted in its middle by the inferior maxillary bone, the upper and lower portions of it bulging out on both sides of the constriction. There was no hæmorrhage worth mentioning. The body and great wings of the hyoid bone could be plainly felt in the posterior recess of the wound. The cyst wall was thin, its external surface quite vascular. The microscopical examination of the contents of the cyst, as well as the primary location of the tumor, revealed its branchial origin. The wound was united with sutures, and a drainage-tube inserted. A compress underneath the chin fastened by a roller bandage, completed the dressing. The next day considerable swelling existed in the mouth, and had caused the sutures to cut through the tissues. The sutures were therefore taken out, and in place of the drainage-tube a pledget of iodoform gauze inserted, with the effect of entirely destroying the unpleasant odor which had arisen during the first 24 hours. In a few days the œdema subsided and the wound in the floor of the mouth had healed by granulation. The difficulty of swallowing and speaking disappeared, and nothing in the looks of the young lady shows any traces of the deformity which was disfiguring her face and neck previous of the operation.

Serous branchial cysts. This variety of branchial cysts is composed of thin cyst-walls and serous contents, and may develop from any one of the branchial clefts which fail to obliterate completely. This affection has been described under the name of *hydrocele colli* (Mannoir), congenital hygroma of the neck (Wernher), congenital hydrocele of the neck, and congenital cystic tumor of the neck (Thomas Smith). Mannoir, under the name of *hydrocele colli*, described certain serous cysts occurring between the angle of the jaw and the mastoid process, and between the larynx and the anterior margin of the sterno-cleido-mastoid, a region which corresponds to the second and third branchial clefts, which were supposed not to be congenital. We have seen, however, that branchial cysts are not necessarily developed during intra-uterine life or soon after birth. All that is necessary is that the matrix for the cysts be present at birth, from which, at some future time, the tumor is developed. These tumors appear as single or multi-locular cysts with thin membranous walls; their internal surface is lined with pavement epithelium. Like a serous membrane, they contain a limpid, watery, or tenacious fluid, holding in suspension epithelial cells and cholesteroline crystals. These cysts

are formed anywhere in the neck, within the area of branchial clefts, between the lower jaw and clavicle. They are usually deep-seated and occasionally superficial. They are painless and give annoyance only from their size. Clinically, they may be recognized from their location, their globular cystic form, soft fluctuating feel and painless growth. The existence of tessellated epithelium upon the inner surface of these cysts has been demonstrated by Neumann and Baumgarten. When these cysts spring from the second or third branchial clefts they are usually deeply located. Hueter,¹ in extirpating a tumor of this kind in a child two years of age, ascertained that it extended between the two carotid arteries back to the walls of the pharynx. When they are deeply situated they are usually in contact, and connected, with the sheath of the large cervical vessels, receiving a distinct impulse from the underlying artery. When thus located they offer the same difficulties to extirpation as the atheromatous variety. The following cases may serve as illustrations of this type of branchial cysts:

*Wernher's case.*² The patient was a healthy female child, which was born with a tumor on the left side of the neck, filling the whole space between the lower jaw and the clavicle, and from the ear to the median line of the neck. The tumor was smooth, tense, elastic, and fluctuating; toward the front part was a small abrasion. Respiration and deglutition were unimpaired. The tumor increased rapidly during the first ten days of the child's life. Wernher, to satisfy the mother, ordered a liniment containing two grains of pot. iod. to an ounce of oil. After a few days a small opening formed through which a dark, brownish-red syrupy fluid escaped for some days. No suppuration. The tumor sensibly diminished. After a time other openings formed in other cysts composing the growth, and the whole tumor began to shrink from the jaw toward the clavicle. Six months subsequently the child died of small-pox, and a post-mortem examination demonstrated that the tumor had completely disappeared.

*Thos. Smith's case.*³ Geo. A., æt. 8 months. Healthy child, and well nourished. At the time of his birth a swelling was noticed behind his right ear, about the size of a hen's egg. This had gradually increased in size up to the time when he was first seen. It was then as large as a fist, and was situated in the posterior triangle, running up behind the ear and toward the angle of the jaw. The tumor was cystic, and evidently contained fluid. In parts it was tense and elastic, and elsewhere it felt flaccid, semi-solid, and lumpy. Smith passed a seton formed of a single thread of fine silk through the most prominent part of the tumor. The immediate result was to diminish the size of the swelling considerably, and subsequently to cause inflammation, suppuration, and discharge from two of the cysts. Three weeks after the introduction of the seton the cysts had quite collapsed, and the tumor had lost about two-thirds of its size. Another seton was introduced, with the result

²Die angeborenen Kysten-Hygrome, Giessen, 1843.

³Congenital Cystic Tumor, by Thos. Smith. St. Bartholomew's Hosp. Rep., vol. ii, p. 16.

of still further diminishing the size of the tumor until it was no larger than a marble.

The same author reports another case, which would show that these cysts may occasionally disappear by spontaneous absorption of their contents. The patient was a healthy babe, 3 weeks old. Immediately after birth a swelling was noticed in the neck, which rapidly increased in size. When first seen, a cystic tumor occupied almost the entire region of the left side of the neck, extending from under the lower jaw to the clavicle. The mother objected to any kind of treatment. Three months later the child was seen again, when the growth had greatly diminished in size. There was nothing to be felt but a loose, flabby cystic mass not much larger than a hen's egg. The skin over it was shrivelled, loose and baggy. Three months later the tumor was still smaller.

That these tumors may sometimes attain an enormous size, is evident from the following case reported by Frederic Treves.¹ It occurred in an infant, and took its origin in the region of the inferior maxillary bone, and occupied the whole side of the neck and upper part of the thorax on the same side, from where it extended as far as the umbilicus. It contained one large and numerous smaller cysts, corresponded to the region of the second branchial tract. No histological report of the specimen.

A very interesting description of a double branchial cyst is given by Vonwiller.² The specimen is contained in the Dresden Anatomical collection. The fœtus, of about 6 months, besides slight abnormalities of the extremities and cleft palate, presents in the region of the neck a tumor nearly double the size of an infant's head, which is divided in the median line by a depression, which separates it into two symmetrical halves. The tumor reaches from the lower margin of the ear and the linea semicircularis of the occipital bone nearly to the apex of the scapula. Larynx and trachea free. Palpation reveals that the tumor consists of two large separate cysts. The skin over the cysts is thin and firmly adherent. The inner surface of the cysts is smooth, and resembles a serous membrane. No projections or remnants of septa can be seen. The septum dividing the two cysts is attached to the middle of the occipital bone and the spinous processes of the cervical vertebræ. It is covered with a similar membrane as the cysts, and separates them completely. The cysts do not communicate with the cavity of the cranium or spinal canal, nor with the mouth or pharynx. The inner surface of the cysts is lined with epithelium, only a small amount of solid contents composed of conglomerations of fatty epithelial cells. The anatomical diagnosis reads: Double branchial cyst—*Hydrocele colli congenita duplex*. The cysts originated, probably, in the cleft between the second and third branchial arches.

I will add another case, which came under my own observation.

CASE IV. *Serous branchial cyst in the fourth bran-*

chial cleft. The patient was a healthy, strong male child, 6 months of age. There is no history of congenital malformation, especially branchial fistula, in the family. When the child was born a small tumor the size of a pea was discovered on a level and somewhat to the inner side of the sternal origin of the sterno-cleido mastoid muscle. The tumor was painless and movable, but rapidly increased in size. When the child was brought to me, it was as large as a walnut. The skin over the tumor was natural in appearance and movable. The tumor itself presented a smooth surface. Fluctuation was distinct, but the cyst appeared to be somewhat firmly attached to the subjacent tissues. The cyst was readily enucleated, the adhesions not being very firm except over the most prominent point of the tumor, where inversion of the skin had undoubtedly occurred during the closure of the external opening of the fourth branchial tract. The adherent portion of the skin was excised with the tumor. The cyst is oval in shape, smooth, the outer layers quite vascular. The walls are thin, the contents serous, which render the whole tumor translucent. The wound was closed with sutures, and healed by primary union under an antiseptic dressing.

4. *Hæmato-cysts of branchial clefts.* In some instances of serous branchial cysts the fluid is discolored by an admixture of blood from minute hæmorrhages into the sac, but when the contents are of such dark color as to resemble venous blood they are properly called hæmato-cysts, and from a pathological, diagnostic, and clinical point of view constitute a distinct and well-marked variety of branchial cysts.

Albert¹ remarks that two kinds of these cysts have been observed: 1st. Such as may be emptied by pressure and are in communication with blood-vessels. 2nd. Those which cannot thus be emptied, and which simulate the appearance of an ordinary serous cyst so closely that their nature is only recognized by puncture. The latter class, when they occur in the neck, usually belong to the branchial cysts, because they are observed during early life and originate in places which correspond to the location of the branchial clefts. This variety of cysts has been called *hæmatocele colli*, by Michaux, and hæmatoma by J. P. Frank. Aside from their origin from branchial clefts, and the admixture of blood with the contents of serous cysts, such cysts may develop from dilated veins, both extremities of the dilated portion undergoing contraction and finally complete obliteration, completely isolating the contents of the cyst from the general circulation. Again, a vein may dilate at one point, forming a pouch or sac, and by contraction and obliteration of the orifice, a cyst is formed. Such a case was observed by Lloyd, in the region of the saphenous vein, and was described by Paget.² A somewhat similar case was examined by Virchow.³ In this instance the disease was complicated by cancer, and the cyst developed from the internal jugular vein, where no communication with the vein could be found. Hæmato-cysts resemble the ser-

ous cysts in every particular, with the exception of the presence of blood in their contents. Their diagnosis, however, is more difficult, and should always be made by exclusion, due attention being given to the location of the cyst, time of development, and character of contents.

Branchial cysts of the neck, as compared with other tumors in this locality, are of rare occurrence. The statistics of branchial tumors cannot be relied upon in estimating the comparative frequency with which these tumors occur, as many branchial cysts have been classified and described under the generic and indefinite term "Cystic tumors of the neck," without regard to their etiology. Gurlt,¹ in 1855, compiled 44 cases of serous, and 6 cases of atheromatous cysts. Since that time quite a number of new cases have been described by Volkmann, Billroth, Esmarch, Roser, Langenbeck, Luecke, and Burow. The serous variety is more likely to develop early; they are often congenital, or appear during infancy or childhood, while the atheromatous cysts are most frequently met with in young adults. Of 53 cases mentioned by Schede²

9 occurred between the						1st and 10th year of life,
21	"	"	"	11th	"	20th
10	"	"	"	21st	"	30th

2	"	"	"	51st	"	60th

Like the dermoid cysts, the branchial tumors show a tendency to develop during the period of puberty, at a time when the epiblast enters upon a new phasis of development, and becomes the seat of renewed and active tissue proliferation. The remnants of the branchial cleft may remain dormant as a matrix for the future growth of the tumor for an indefinite period of time, and become the seat of tissue growth during puberty, or upon the advent of any determining cause or causes. There are undoubtedly many instances where remnants of foetal tissue remain latent in the branchial tracts throughout a lifetime for want of an adequate exciting cause, which is necessary to call into morbid activity the slumbering forces inherent in the histological elements of the matrix.

Diagnosis. To diagnose the presence of a branchial cyst, is often no easy task. The importance of the tissues and organs which are in close and intimate relation with these tumors, renders it imperative upon the surgeon to make a correct diagnosis before an operation is undertaken for their removal. All witnesses should be examined carefully, and every diagnosis should be fortified by eliminating the existence of all other forms of tumors. The following conditions may simulate a branchial cyst: 1, Aneurism; 2, angioma; 3, dermoid cyst; 4, retention cysts; 5, affections of lymphatic vessels and glands; 6, struma cystica; 7, simple serous cyst.

1. **Aneurism.** As most of the branchial cysts are in immediate contact with the large cervical vessels and usually receive the impulse from the underlying artery, it is always important to exclude the possible presence of an aneurism. At the age when branchial

cysts are most frequent, aneurisms, except of traumatic origin, are exceedingly rare. Pressure does not affect the volume of a branchial cyst, and the pulsations are felt only in one direction, away from the artery. Auscultation furnishes another important negative symptom. An exploratory puncture, which should always be made in doubtful cases, will also furnish valuable information, as it will afford an opportunity to examine the contents of the cyst under the microscope, and such examination will not only help to substantiate the diagnosis, but, in many instances, will by itself be sufficient to arrive at positive conclusions. In hæmatocysts, the contents may resemble venous blood, but a microscopical examination will show in addition the presence of epithelium or the products of epithelial degeneration.

2. **Angioma.** Deep-seated angiomata of the neck are occasionally met with in children, and as the skin may present a perfectly natural appearance they might be mistaken for a branchial cyst. If the tumor disappears under pressure, it may be an angioma, but never a branchial cyst.

3. **Dermoid cyst.** As dermoid cysts may occur in the same localities, and at the same age, they are frequently mistaken for branchial cysts, and *vice versa*. A number of authors classify deep-seated atheromatous cysts with dermoid cysts. As both varieties of cysts require the same treatment, a positive diagnosis is not essential. A correct anatomical diagnosis can be made by examining the contents and the cyst walls. A branchial cyst contains only one constant histological element—epithelium, as obliteration of the branchial tracts takes place long before the appendages of the skin are developed. A dermoid cyst, on the other hand, as its name implies, contains the products of secretion of the skin and the organs which it contains, the hair follicles, the sweat, and sebaceous glands. Lanuginose hair and hair follicles are never present in a true branchial cyst, while they are frequently found in the contents of dermoids. The walls of a branchial cyst are composed of a connective tissue capsule lined with epithelium, while on the other hand, the sac of a dermoid cyst is composed of true skin.

4. **Retention cysts.** The only two forms of retention cysts which call for consideration in this connection are the true atheroma of the skin, the result of obstruction in the ducts of the sebaceous glands and the retro-tracheal cyst, which originates in a similar manner in the retro-tracheal glands. Cysts arising from the second and third branchial clefts are always deeply located, and when first observed are distant from the skin, while an atheroma primarily develops in the skin, and usually grows in a peripheral direction. Branchial cysts are always congenital, atheromatous cysts acquired. Lanuginose hair is sometimes found in the contents of an atheroma, the product of retained hair-follicles; it is never seen in branchial cysts. Another important anatomical difference will be found in the outer portion of the capsule of the cyst and its relation to the surrounding tissues. In branchial cysts the capsule is quite vascular, and intimately connected with the adjacent structures, the reverse being true of the retention cysts.

¹ *Archiv für Klin. Chirurgie*, vol. xiv.

² *Die Cystengeschwülste des Halses*. Berlin, 1855.

Virchow¹ has called attention to a peculiar kind of retention cyst between the œsophagus and the trachea arising from an obstruction in the duct of one of the retro-tracheal glands. These glands are situated between the trachea and the œsophagus, but their ducts traverse the entire thickness of the tracheal wall and terminate upon the free surface of the mucous membrane. These cysts are so located that they give rise to distressing symptoms referable to deglutition and respiration before they attain any considerable size, and before their existence is suspected or detection is possible, differing greatly in this respect from the clinical history of a branchial cyst.

5. *Affections of lymphatic vessels and glands.* A deep-seated isolated caseous lymphatic gland might be easily mistaken for a branchial cyst, more particularly after the cyst had become the seat of inflammatory infiltration. Luecke² claims that he has observed the development of dermoid cysts within lymphatic glands. It is seldom that we meet any such extensive pathological changes in a single lymphatic gland to such a degree as to simulate a branchial cyst, without participation of one or more adjacent glands. Again, in cases of disease of the lymphatics the general condition of the patient usually indicates the existence of a serious affection, while a branchial cyst is a purely local condition, never affecting the general health of the patient, except when by compression it interferes with important functions of neighboring organs. Köster is of the opinion that many of the multilocular cysts of the neck are the result of lymphangiectasis, but in such cases a microscopic examination would show the presence of endothelia which would exclude the branchial origin of the tumor. Cancerous or sarcomatous affections of the lymphatic glands would reveal themselves by the clinical symptoms characteristic of these tumors.

6. *Struma cystica.* Cystic degeneration of the thyroid gland proper can never be mistaken for a branchial cyst, as the connection of such cysts with the thyroid body can be traced without any difficulty, but recently it has been ascertained that not infrequently small accessory thyroid glands exist in the neck which may undergo cystic degeneration, and Madelung has made the assertion that the so-called hydrocele of the neck is only a struma cystica of a supernumerary thyroid gland. The possibility of a cystic degeneration of such an accessory thyroid body should always be borne in mind in all examinations for branchial cysts.

7. *Simple serous cysts.* Virchow asserts that many of the serous cysts develop without a particular matrix, as new formations in the connective tissue. It is a well-known physiological fact that the connective tissue cells are occasionally converted into endothelia, as during the formation of new synovial membranes, hence we should *a priori* expect that in simple serous cysts developed from connective tissue the inner surface of the sac would be lined with endothelia, the existence of which would be sufficient to disprove their branchial origin.

Cystic degeneration of the ganglion caroticum has been supposed to resemble branchial cysts. Luschka¹ has described a ductless gland between the external and internal carotid arteries, near the bifurcation of the common carotid, to which he has applied the term ganglion caroticum. As this gland is located where branchial cysts usually are found, he has made the assertion that many of the cysts in this region are due to a cystic degeneration of this gland. To cysts originating in this manner he has applied the term *hygroma colli*. The researches of Julius Arnold, however, do not corroborate the observations of Luschka, and Virchow positively denies the glandular nature of this body.

In repetition I will enumerate the following points, which should be considered in the differential diagnosis of cystic tumors of the neck and with special reference to branchial cysts: 1. Primary seat of tumor. 2. Effect of pressure. 3. General condition and age of patient. 4. Character of contents.

Prognosis. Branchial cysts, although heterologous formations, always remain purely local affections and manifest no tendency to destroy life, except when they are of sufficient size to interfere by their presence with the performance of important functions of neighboring organs. On the other hand, it may be said that they manifest no tendency to spontaneous cure and prove exceedingly rebellious to all forms of treatment short of complete extirpation. The serous variety in exceptional cases may undergo spontaneous absorption, and, as a rule, is most amenable to the milder forms of treatment. After the development of these tumors, their further growth may become stationary for a short time, but their tendency is to increase in size until they encroach upon important organs, when the suffering and distress which they occasion call for decided and effective operative measures for their removal.

Treatment. The inner surface of branchial cysts being lined with epithelium, it is evident that obliteration of the sac can only be obtained after the destruction or removal of this epidermal lining. The radical treatment for the removal of these tumors must have for its object the production of an artificial inflammation in the interior of the sac of sufficient intensity to destroy the epidermal matrix, or complete extirpation of the cyst. The former procedure is exceedingly unreliable in its results, and extirpation in many instances must be looked upon as a very formidable and dangerous operation. The following methods have been resorted to in the treatment of branchial cysts: 1. Incision. 2. Actual cautery. 3. Seton. 4. Puncture with subsequent injection. 5. Extirpation. 6. Antiseptic drainage.

1. *Incision.* In all cases where incision was practiced, the relief from existing symptoms was prompt; the cyst collapsed, a certain amount of inflammation was established, suppuration followed, and, in some instances, the patient and surgeon were led to believe that a radical cure was obtained. Usually after healing of the wound a small nodule remained, which in a few months again became the seat of active tissue growth, and a speedy relapse was an almost constant

¹Die Krankhaften Geschwülste. Berlin, 1863. Vol. i, p. 246.

¹Virchow. Op. cit. vol. iii, p. 93.

occurrence. The result was not materially modified in case the sac was drained and injected with iodine or other irritating solutions. In infants the laying open of cysts is a perilous plan of treatment. Volkers relates a case where a cystic tumor was laid open in a new-born child who died 16 days afterward in consequence of the operation. A branchial cyst cured by simple incision is reported by Billroth. In the case of serous cysts where the seton and iodine injections have occasionally been successful in producing obliteration, it seems to me that the same object would be accomplished more speedily and safely by incision and drainage, practiced in a similar manner as in Volkmann's operation for hydrocele.

2. *Actual cautery.* Dieffenbach employed the actual cautery in opening the cyst in one of his cases after he had made an unsuccessful attempt in removing it by extirpation, and after incision had failed in producing obliteration of the sac. The use of the cautery met with no more encouraging result. It would seem to me that incision combined with an energetic use of the cautery would be most applicable in the most dangerous and formidable class of cases, namely, in cysts which have become firmly adherent to the sheath of the cervical vessels by repeated attacks of inflammation. Should I ever meet with a similar case as the one reported in this paper, where the internal jugular vein was injured, I should make a free incision into the cyst, and after removing as much of the sac as would be compatible with safety and after exposing to sight the floor of the cyst, I should destroy the entire epidermal matrix of the attached portion with a Paquelin cautery. The wound could be sutured and dressed the same as after excision, by which primary union of the wound with complete destruction of the matrix of the tumor could be secured, without exposing the patient to the much greater risk of injury to the internal jugular vein which would be incurred by attempting complete extirpation.

3. *Seton.* This form of treatment proved successful in several of Thos. Smith's cases of serous cysts of the neck, but in some of them the branchial origin of the cysts does not appear to be established. Smith¹ uses a single thread of silk, and removes it before suppuration sets in. If the tumor is polycystic, he attacks only one cyst at a time. Gurlt very justly has entered his protest against the use of the seton. Like in hydrocele, the seton is an exceedingly uncertain agent in calculating with precision the amount of inflammatory action which will follow its use. The degree of irritation produced by it is very liable to be inadequate to produce adhesion, or it exceeds the desirable boundary and induces suppuration with all its evil consequences. Even the seton is not devoid of danger. Butlin reports the case of a young child where a seton was passed through a serous tumor, and which was followed by death on the third day from the violence of the inflammation.² For this and other obvious reasons the seton should never be used in the treatment of branchial cysts.

4. *Puncture with subsequent injection.* In the

transactions of the fourth Congress of German Surgeons the treatment of branchial cysts by puncture and injection was fully discussed.¹ Esmarch's experience appeared to be the most extensive, and his results were more uniformly favorable than in the practice of any other surgeon. The following are some of Esmarch's remarks on this subject:²

"I have cured about a dozen cases by puncture and subsequent injection of Lugol's solution of iodine. (Iodinii, pot. iod. aa 1.25, aquæ 30.c). Against this treatment it has been urged that complete extirpation of the cyst can always be done and is free from danger. I must deny this assertion, because in a majority of cases the cyst is adherent to the sheath of the internal jugular vein, a fact which may remind you of a paper on this subject by Prof. von Langenbeck, which served as an introductory to his Archiv in 1860. In this paper Langenbeck called special attention to the dangers connected with this operation. But even if the operation were free from danger, yet by resorting to it we obtain an unsightly cicatrix in the neck, to which the female sex objects. I can, on the other hand, recommend injections of iodine as an efficacious and entirely safe procedure. If some of you have failed to see its benefits, it is, I believe, because you have not had the necessary patience and perseverance. As a rule, I have repeated the operation whenever obliteration did not promptly follow the first puncture. It is very essential to irrigate the sac thoroughly before the introduction of the iodine. I have generally proceeded as follows: By means of a fine hydrocele trocar I empty the sac of its contents, and then make repeated injections of a one per cent. solution of carbolic acid. This removes the masses of epithelium adherent to the cyst-wall. I continue these injections until the water returns perfectly clear, and then I inject 10–20 grms. of Lugol's solution of iodine, which, after gentle pressure to bring it in contact with the inner surface of the sac, is allowed to escape. The patient is then directed to return in six or eight weeks. Like a hydrocele, the cyst refills rapidly and becomes somewhat painful. If, after the lapse of time mentioned, it has not greatly decreased in size, I repeat the same operation, and tell the patient to return in six months, when the cyst will be found atrophied to a small tubercle. In most cases the cure has been permanent."

In the discussion which followed, Langenbeck said: "I have treated a number of dermoid cysts with fatty contents by means of injections of iodine, but the injections always required repetition. I punctured the cyst with a large trocar, introduced a piece of elastic catheter and made daily injections. A few cases were cured after three or four injections. In one case the tumor returned. I consider it very difficult to cure these fatty cysts with injections of iodine or any other substance."

Roser admitted that injections of iodine might succeed in serous and mucous cysts, but that they would prove of no avail in atheromatous cysts. Baum asserted that extirpation was an easy matter, and that these cysts could be removed without difficulty.

¹Op. cit.

²International Encyclop. of Surgery, New York, 1884. Vol. iv, p. 663.

¹Verhandl. der deutschen Gesellschaft f. Chirurgie, 1876, p. 25.

²Op. cit., p. 129.

Bardeleben believed that some of these cysts, especially those which extend behind the sternum, could not be extirpated, but obliteration in one instance was accomplished by antiseptic drainage. Volkmann spoke in favor of extirpation and warned against injections of iodine, as in case of failure they would render a subsequent excision more difficult.

It is evident that the majority of German surgeons who have given a good deal of attention to this subject have no confidence in the efficacy of iodine injections in obliterating branchial cysts. If we consider the numerous failures of iodine injections in cases of hydrocele, where the anatomical conditions for success are so much more favorable, we will be better prepared to appreciate the causes of its still more frequent failures when used in the treatment of branchial cysts. Again, clinical experience has shown that branchial cysts can be extirpated with comparative ease and safety before the cyst has become firmly fixed to the subjacent cervical vessels by inflammatory infiltration and that in this class of cases iodine or any other injections will not only prove useless, but will render a subsequent extirpation still more difficult. In infants even simple tapping is not always devoid of danger, as one instance is recorded of death caused by puncture. The case occurred to Volkers, who tapped a cystic cervical tumor in an infant eight days old, the child dying of trismus on the third day.¹

5. *Extirpation.* A positive diagnosis made, the best plan to pursue is to make an incision over the most prominent portion of the tumor, and, in case the adhesions can be separated without endangering the deep cervical vessels, the entire cyst should be removed. If inflammatory infiltrations obscure the field of operation at the base of the tumor, and after careful examination it is not deemed advisable to perform complete extirpation, the sac should be opened and the lateral walls excised, and the epidermal matrix, which remains adherent to the sheath of the cervical vessels, can be destroyed completely by a careful but vigorous use of the actual cautery. The treatment of the wound should be conducted as in cases of complete excision. If an early diagnosis is made, and prompt treatment instituted, complete extirpation should always be attempted, and will in the majority of cases prove successful and comparatively free from danger.

6. *Antiseptic drainage.* In the case of infants and very young children suffering from large serous cysts, it would be imprudent to resort to any of the severer measures with a view to a radical cure. In such instances, drainage under antiseptic precautions should be resorted to as a temporary measure, and in some instances it may be followed by permanent results. The same course of treatment should be adopted in adults suffering from cysts which are inaccessible to any other operation, and in which irritating injections are contra-indicated.

A COMBINED VISUAL AND ASTIGMATIC TEST-CARD OF WORDS MADE UP OF LETTERS CONFUSING TO THE ASTIGMATIC EYE---REMARKSON ASTIGMATISM, CHARACTERISTIC MANNERISMS.

BY WILLIAM S. LITTLE, A.M., M.D., PHILADELPHIA, PA.

Read in Section on Ophthalmology, Otology and Laryngology of the American Medical Association, May, 1884,

The influences of optical defects are three-fold; first, productive of vision less than normal; second, are productive of certain ocular diseases or render acute attacks of eye disease chronic by their presence; third, there are produced by their presence, headache, nervous symptoms, gastric disturbance, many cases of so-called biliousness and a chain of reflex symptoms due to the accommodative effort. Cases presenting a manifest defect of vision, seek relief by glasses, and are satisfied either partially or fully, as the manifest or total defect is corrected. In cases where ocular disease, or the form of trouble described under the third classification exists, accommodative effort may conceal the defect, which any of the mydriatics will expose and relieve the symptoms if they are the result of the optical condition of the eye; glasses are required to take the place of the therapeutic action of the mydriatic, and they represent the accommodative effort, which is not natural to an emmetropic eye.

Simple myopia or hypermetropia is productive of trouble in a small proportion of the cases under the second and third classifications, but more prevalent in the first. The myopic or hypermetropic forms of astigmatism are the more frequent condition in the last two classifications; either alone, simple astigmatism, or combined, the former with myopia, the latter with hypermetropia, compound astigmatism; or the two forms of simple astigmatism may co-exist, forming mixed astigmatism.

In a paper I read before the American Ophthalmological Society, 1880, a tabular report exhibiting the position of the axis of the cylinder in simple, compound and mixed astigmatism, the myopic and hypermetropic form compared, with remarks, (Transactions, 1880), it is stated that simple astigmatism is present in 45½ per cent., compound astigmatism in 50 per cent., mixed astigmatism in 4½ per cent. of cases of abnormal astigmatism. A continued experience in refraction imposes a stronger belief of the influence astigmatism has as an optical defect in producing trouble, especially in the third classification.

While an instrument of precision, like the ophthalmoscope, enables these defects to be recognized, by either the direct or indirect method, or by keratometry or retinoscopy, the instrument must be properly handled, which is not difficult if undertaken to be learned, and though numerous visual tests already exist to enable the defect to be exhibited by a patient, they require a proper understanding to attain a diagnosis; and several tests have to be appealed to instead of one.

¹Dr. Storch, Ueber das angeborene Hygrom des Halses. *Journal für Kinderkrankheiten*. Vol. xxxvii, p. 68.

It has been my desire to put in the hands of the medical profession a visual test that will exhibit manifest defects more markedly, and bring out to a greater degree latent defects without a mydriatic, than I have found the various useful tests already devised seem to do, especially for the recognition of abnormal astigmatism; also, to express by the test a value for the defect as it is exhibited by the patient.

A point of light of a given size at a given distance, is sufficient to demonstrate all optical defects, especially astigmatism, certain conditions being obtained to render it fully effective; other simple methods to recognize astigmatism are the inability to recognize with equal definition, at a given distance, the radii of a circle of a given size; or call a letter O an O. Dr. Pray's astigmatic letters; Dr. John Green's test diagrams for the detection and measurement of astigmatism; Dr. Wm. Thomson's ametrometer; Javral's instrument, and numerous other valuable methods, by foreign and home observers, are at hand, based on given fixed laws in optics.

The letters in Snellen's type, or in all other letter tests, will exhibit the astigmatic defect; by the way the person tested expresses the name for the spherical and right-angled letters in the test; O is called C or G; F is called P; B is called S; the reverse holding; they distort the letters and are confused.

In simple myopia or hypermetropia with normal astigmatism, no such distortion or confusion occurs, but total obliteration of a letter of a given size, at a given distance according to the degree of the trouble.

This fact of the distortion of the letters by astigmatic eyes, has long been recognized and was spoken of by Dr. Reynolds, of Louisville, at the meeting of this Section of the Association at Richmond, in 1881; I then stated I had used this distortion, as a means of diagnosing astigmatism.

During the past year, I have been trying the value of a test, based on this distortion and confusion of letters, and now present it to the medical profession, especially general practitioners.

The letters most frequently distorted have been selected from Snellen's type and formed into a word; underneath this word have been placed the letters of the same word, as they appear to an astigmatic eye, so that a person affected, will say, that each line of letters is alike, and the word in the upper line and letters in lower line, are the same word; no dissimilarity existing as there would be to an emmetropic eye.

To give an approximate mathematical expression to the degree of the defect, manifest or latent, in myopia or hypermetropia (simple) or in astigmatism of all forms, the size of the letters are graded in the word from $D=18$ to $D=6$. Four letters being taken to form the word and four letters in the confusion line below it, same grade and size of letters under one another. The word FOOL has been selected. In an astigmatism of 1. D manifest or after use of a mydriatic, the test being made from 6 meters, the size of the last letter in the word being $D=6$, F. is called P; each O in turn is called C; L is called I; — PCCI underneath FOOL appears the same as FOOL itself, and are stated to be similar in

appearance or nearly so. Astigmatism 0.75 D will distort the last three letters in the word at 6 meters, that of 0.50 D the last two letters, that of 0.25 D the last letter at 6 meters.

In simple myopia or hypermetropia with normal astigmatism of 1. D at 6 meters the whole word will be unrecognized and the letters underneath as well; no distortion or confusion occurring, but obliteration from spherical defect.

To obtain the position of the good and bad meridians in astigmatism, the horizontal lines, one above FOOL, the other below PCCI, will enable this to be found out by rotating them horizontally, vertically or obliquely to either side before the patient; the size of the lines are each $D=9$. Cited at 6 meters, both are seen clearly in one position and not at right angles to this position, the astigmatism is 0.50 D or more, the axis expressed by the angle they are held, defect same at 9 meters also. The word COCOON $D=9$, letters uniform size, if distorted at 6 meters $V=\frac{6}{9}$, 0.50 D astigmatism exists or more; A illustrates the same principal as in FOOL and PCCI, only combined in one word and in one line of uniform size; it is a very expressive test and defects are rapidly recognized by it.

For astigmatism higher than 1. D the same type must be brought nearer to exhibit the defect; but in place of this, the word NULLIFIED graded in size from $D=60$. to $D=4$. can be used; they are confusion letters, and in the letters above the letter $D=18$, a defect higher than 1. D will be recognized from either 4 meters, or better at 6 meters; the higher the astigmatism the larger the letter confused. The word NULLIFIED has been placed at the top of the card and can be used to express visual power, as Snellen's type or others, is to be seen in full from 4 meters, the last letter in the line $D=4$ thus recognized in full. $V=\frac{4}{4}=1$ as a letter in list as confused $V=\frac{4}{5}-\frac{4}{6}-\frac{4}{9}-\frac{4}{12}-\frac{4}{18}-\frac{4}{24}-\frac{4}{36}-\frac{4}{60}$. It is to be brought nearer in higher defects; as $V=\frac{3}{60}-\frac{2}{60}-\frac{1}{60}$, the numerator of the fraction being the distance in meters from which the test is made. At 6 meters $D=6$ is last letter recognized.

The word SUFFICIENT, ranging in size from $D=24$ to $D=1$, is also composed of confusion letters and as a confusion word, is introduced so that the test can be as accurately made in offices that are restricted in size, as well as in large ones, the last letter being $D=1$, to be tested from one (1) meter. At 6 meters S, in the word $D=24$, will be called B in astigmatism higher than 1. D.

I have adopted the metric system, which is readily convertible into the English foot or French scale.

Manifest defects give more of the defect to be recognized by this test, I find, than by other or more latent conditions can be detected; a mydriatic is required to give the total defect and obtain full effect in correcting all optical defects; certain ocular conditions rendering it unnecessary or dangerous; in the correction of astigmatism there is no half-way, the whole defect must be recognized under a mydriatic.

It must be looked upon as a deformity. Especially

is this so in the cases under the second and third divisions I made in the early part of the paper; for to medical men the connection of optical defects with disease are principally interesting and useful as surgical or therapeutical means to obtain relief, the same as any other plan that might be adopted. In addition to these cases, the ophthalmic surgeon is called to treat largely the first class of cases, those with diminished power from all causes, among which optical defects have a decided prominence.

The test may be made to answer a use in studying the visual field, using the word NULLIFIED at $\frac{1}{2}$ a meter, closing one eye and fixing the other eye on the centre of the word and seeing it without moving the eye, the other letters can be recognized; placing the word horizontally, vertically or obliquely to either side will enable limitations or sectoma to be made out. While the test has been devised principally for the recognition of all optical defects, being founded on a scientific basis, as all such tests are, it is accurate for the correction of such defects and for proof of work done by other accepted and necessary tests at the hands of the ophthalmic surgeon.

The presence of abnormal astigmatism, especially of a high degree, can be recognized in a case, without subjecting the patient to a visual test, or an ophthalmic examination; certain characteristic mannerisms exist.

An emmetropic eye can swing around a circle, recognize a letter c with ease; the abnormal astigmatic eye is confined to a tight-rope constraint of visual power, which not only affects his sight, but his idea of objects looked at and the impressions made in his brain; he is constantly annoyed; as a person endeavoring to catch a ball with only one finger on each hand.

The position of the head, held at an angle, depending on the position of the axes of the good or bad meridian, gives them a peculiar pose; the narrowing of the palpebral fissure of the eyelids, to compensate for the defect, mars their facial expression and produces in youth the wrinkles of old age, about the eyes and forehead. The use of opera glasses, microscopes, telescopes, do not give the satisfactory results as to the perfect eye; seeking aid by spherical glasses they find none.

The design of the material of a costume, the selection of wall paper, carpets in a home, display their characteristic sight.

When the ciliary muscle gives way in the attempt at compensation, they become sufferers from bilious headache, which a darkened room and closed eyes for a day or two relieves; not the medicine taken; they begin again; till exhaustion follows again; such cases are literally sea-sick on land, on the high sea they are not sufferers from looking at the movement of the waves, as an emmetropic eye may be; to such cases with perfect eyes a pair of strong cylindrical glasses will give comfort, as the astigmatic eye finds relief in removing their correcting glass.

That certain cases of seasickness are due to annoyance from this movement of the waves, is a fact, and the suggestion of prevention by cylindrical glasses is

only made to those so affected, other causes of seasickness not being considered. A personal experience with and without correction and statements from other persons so afflicted, justifies the statement of the fact. In our schools and colleges, theological seminaries and later literary life, also in the arts, astigmatism produces the greatest annoyance.

Letters and words are viewed that require a spherical eye to convey them to the retina, then to cause ideas in the brain and obtain results. Such persons work at great advantage; there is no distortion of letter, confusion of words, nor working at great odds in obtaining ideas. The astigmatic eye has its own letters and words; they are always uncomfortable, as a person translating a language with a dictionary at hand; the extra labor, uncertainty, mistakes, discouragements, often classified as stupid, render a literary life distasteful. If persisted in, health is impaired and serious lesions are produced in the eye itself. In the arts, a longer time is taken to do a given piece of work, and then not so well done.

There is no reason so potent for abolishing Greek from the schools and colleges as the inability of the astigmatic eye to recognize its characters readily, the frequency of the defect, renders it distasteful to students and a great annoyance in studying it.

The fate of a friend in scanning Homer often resulted in his teacher's saying, "sit down 'ονος,'" when he gave that word for "αυος," and the solid contents of the book not infrequently was attracted to the master's head, as a result of the indignity to his student.

The Hebrew type in the theological seminaries, and the German type are equally as annoying. The musical score is subject to the same criticism. The Roman letter should prevail for all these languages, as that is sufficiently troublesome to an astigmatic eye, but less so than other type. German medical works are largely in Roman type, and a recent statement that 800 medical men in New York City were studying German is not to be wondered at.

I am greatly indebted to J. W. Queen & Co., of Philadelphia, Pa., for the manner in which the test has been lithographed for use by the profession.

In addition to this test, I have been using for some time an arrangement of Dr. Pray's astigmatic letters, combining them into two words under one another, PUBLIC NOTICES. It gives an opportunity to locate the good meridian quickly, and after correction of the defect, is a good proof of the correctness of the work.

The size of the lines in the letters should be $D=12$ or $D=9$. This test has not been lithographed.

To produce a test for the near point on the plan of the test first described is not necessary, the same confusion of words after distortion of letters will be found to exist for the near as the far point. So selecting these words in the text of Snellen or others at the proper point and using the proper size, the same will be found to exist.

The effects of astigmatism are constant, and the correction of the defect requires the constant use of glasses for far and near.

DISCUSSION.

Dr. J. L. Thompson thanked the essayist for his very interesting and instructive paper, but protested against that portion of it which would dispense with a mydriatic in the examination of all anomalous refraction. He was fully convinced, after abundant proof in going over the work of others, that no man on earth has ever been able in all cases to prescribe glasses correctly without the use of a mydriatic. If he was not permitted to thoroughly examine a patient, he would not think of prescribing; but when one has thoroughly examined his patient, then he is not ashamed to have his work go before the world. He would not accept a fee in these cases unless the patient consented to this test.

Dr. D. S. Reynolds, of Louisville, Ky., said that no accurate diagnosis of astigmatism could possibly be made without the aid of a mydriatic. He had tried it in his own and many other cases, and had found no other method reliable.

Dr. S. M. Burnett—I never use a mydriatic, unless I have reason to believe there is spasm of accommodation. I am decidedly opposed to its routine employment.

Dr. E. D. Theabold, of Baltimore, Md.—I wish to enter my protest against the use of a mydriatic. We do not correct the latent, but simply the manifest anomaly, and in cases of myopia it is entirely unnecessary.

Dr. Shakespeare, of Philadelphia—I fully agree with the gentleman who first spoke as to the impossibility of correctness in many cases short of mydriasis; have astigmatism myself, and find that while I now look at the texts of the essayist, they do not lead me to his conclusions. Have examined myself before and after artificial mydriasis, and have reexamined many others, and am fully confirmed in my belief as to the importance of this acid.

Dr. S. D. Risley—Like all of the refinements brought to our aid during the last few years, I fear that this, also, will not prove of very great practical benefit; as in my own case, while looking at the texts it does not answer expectation, so will we doubtless find when we have to deal with confused or stupid persons. Very skilful opticians constantly claim ability in this direction, and yet we see how frequently they fail in their efforts. I, therefore, declare very positively in favor of the use of a mydriatic.

Dr. L. Connor, of Detroit, Mich.—I first examine without, and afterwards with, a mydriatic; always use it where I suspect muscular spasm.

Dr. Young, of Iowa—In a majority of cases you get a different effect where a mydriatic has been used.

Dr. R. J. McKay—If the patient first looks at test types without, then with glasses, and we also examine with the ophthalmoscope, we can usually determine the astigmatism without mydriasis.

Dr. W. S. Little, in closing said—I am a full advocate of a mydriatic, except where there is a tendency to glaucoma, or in cases where the age of the patient renders it unnecessary.

NASAL POLYPUS OCCURRING IN A PATIENT THIRTEEN YEARS OF AGE.

BY E. FLETCHER INGALS, M.D., CHICAGO, ILL.

The following case is of special interest as a contribution to the history of mucous polyps in the nose because of the patient's age.

Growths of this character are extremely rare in patients less than sixteen years of age, and the history in this case shows that the polyps were present during the patient's thirteenth year, and may have had a much earlier origin.

Miss M— at fourteen came to me from Minnesota last July, complaining of catarrh, and difficulty in breathing through the nose, which had caused her great inconvenience for twelve months.

She had been troubled with cough and considerable expectoration for eight years, and the usual symptoms had existed several years, though not so markedly as during the past year.

Upon examination of the chest, I found the râles of chronic bronchitis, with no evidence of consolidation or emphysema. The larynx was slightly congested. The naso-pharynx relaxed and bathed in secretions, but free from abnormal growths.

Anterior rhinoscopy revealed large mucous polyps nearly occluding both nares.

These growths evidently sprang from the middle meatus or external surface of the middle turbinated bone and had the characteristic appearance and feel of myxomata in this locality.

I removed them thoroughly with the steel wire écraseur and applied chromic acid to their bases. The acid was applied by means of a flat aluminium probe upon the end of which a very small quantity had been fused by gentle heat.

Chicago, August 14, 1884.

MEDICAL PROGRESS.

MEDICINE.

ON THE CAUSES OF COLORED SWEAT.—Drs. Balzer and Barthélemy have been making some recent observations upon this subject, which has of late attained importance through the micro-chemical examinations reported by various observers. They confirm more especially the observations of M. Babes, who found a particular form of microbia to be present with certain micro-chemical and spectroscopic characteristics, and who succeeded in cultivating the microbia in coagulated albumen. They give first (*Annales de Dermatologie et de Syphiligraphie*) the details of a case, where in a male subject, 34 years of age, who perspired freely at all parts, the axillary sweat alone was of a brownish, or brick red color. The hair in the armpits was of a dull reddish color and wanting in pliability, irregular in calibre, and matted together.

The parts were regularly and carefully washed and bathed with cologne water, and alkaline applications were also made, but to no effect. Sulphur, corro-

sive sublimate, borax, chloral, salicylic acid, thymic acid and carbolic acid were all in turn given a fair trial in solution, but without benefit. They were used also upon the detached hairs by maceration. Aromatic vinegar seemed to have some influence, as well as chloroform; ether had the decided effect of removing the color at the end of several days.

After noting this case carefully, these observers had several other cases of red or yellow sweat from which they made preparations of the detached hairs, which were first deprived of their fatty principles by alcohol, and then mounted in glycerine or balsam, others were subjected to the action of the various staining fluids. By the use of a moderate power they were seen to be completely invested with yellow or reddish masses, frequently separated by naked spaces, giving each hair a peculiar knotted appearance. Sometimes there was but a thin, reddish layer on the surface of the hair, with others the parasitic masses were agglomerated and superposed so as to completely hide the hair itself. Radiating striæ were seen converging towards the hair, with a glutinous amorphous substance between the striæ. On using a high power these striæ were seen to be formed by chaplets of round or elliptical micrococci presenting a yellow, brown or red color. The substance surrounding and agglutinating them seemed to be of their own exudation, and was itself colored. They were attached to the epidermic layer of the hair, and particularly at eroded points. Whilst the cortex of the hair remained intact, the parasite did not extend over much surface, but when the cortex became degenerated by maceration or by the cleavage which was produced through the parasitic masses penetrating between the layers of the hair cortex, the hair was filled throughout with them. The scrapings of the epidermis also showed them in considerable quantity, but they were not all colored red; some were colorless, and masses were seen partly colored and partly colorless, with numerous microbia of a different species.

In a general way, the red sweat seems to affect especially feeble, lymphatic, arthritic individuals, convalescents or debilitated persons. It seems to occur more frequently in red, blonde, or brownish-red subjects. Since their attention was directed to the subject they have examined a number of subjects that did not have the colored sweat, and are convinced that the parasiticism of the axillary region is very common as well in those persons who are of careful, cleanly habits as in careless, dirty persons. But this parasiticism is not always accompanied by the red color, a very feeble yellowish color, or none at all is noticed. If the parasitic masses from these persons are examined, they appear like dried gummy matter; the microbia appear to be the same, but a little yellow or colorless. The abundance of the perspiration evidently favors the multiplication of the red microbia, but it would appear that up to a certain point the coloring of these micrococci increases independent of their surroundings. M. Babes considers it possible that they are contagious.

Moreover, red sweat is not confined to the axillæ. the scrapings from the inguinal and perineal region will give similar microbia, and the hairs from these re-

gions give the same appearance as already described. This has also been seen in the hairs from the beard of certain subjects.

As to the treatment, it is well to remember that this condition appears frequently to be the result of general fatigue or debility. It is only by studying the composition of the sweat that the conditions which favor the development of the micrococci can be arrived at, and a rational local treatment determined upon.

A CASE OF DYSTROPHIA AND OF SPONTANEOUS FALL OF THE NAILS IN GENERAL PROGRESSIVE PARALYSIS.—Dr. Regis (*Gaz. Méd. de Paris* and *Jour. de Méd. de Paris*) gives a case of this affection, the characteristics of which have been before noted by MM. Joffroy and Pitres during the past two years in ataxics. Dr. Regis gives his observations in a case of general paralysis, where the nail of the left great toe was very much altered in its form, texture, and coloration, looking like the scale of an oyster shell, and was ready to drop off, only adhering slightly by the root; beneath it was a little pus, which could be made to exude on pressing down the nail. On the right side the nail of the great toe was more dystrophic, and showed clearly on its superior surface alternate transverse depressions and ridges, and in its thickness a special stratification of the lower layer which was friable and pulverulent. This nail lay upon a thin layer of pus. Soon after the nail of the left great toe detached itself spontaneously, and a month later, from a slight blow, the nail of the middle toe fell off. The sensitiveness of the tissue surrounding the nails was very much blunted. The nail of the left great toe has been reproduced, but in such a rudimentary manner as to appear abortive. The nail of the right great toe has not yet come off. The nail of the right middle toe has not been reproduced.

Dr. Regis has noted this alteration of the nails in a number of cases of general paralysis. Moreover, this lesion is not limited to the toes, as with ataxics; the nails of the fingers are also attacked. The patient has had syphilis, it is true, but these deformations belonged to the general paralysis.

MATERIA MEDICA AND THERAPEUTICS.

DIRECT GALVANIZATION OF THE STOMACH.—Dr. G. Bardet, in the *Bulletin Generale de Therapeutique*, gives us his method of employing this means of relief in cases of dilatation of the stomach accompanied with atony, and in cases of spasmodic nervous vomiting. He reports four cases, of which three were positively benefited. It seems that, while it is common to recommend the electrization of the epigastric region, the direct galvanization of the stomach by the use of special electrodes has been used but by two authorities, viz.: Perli, 1879. used this means while washing out the stomach at the same time with the stomach pump for dilatation and chronic catarrh. He used a sound ending in metallic olive-shaped extremity, and carrying a conductor in its interior, which was con-

nected with an induction apparatus. He obtained in this way vigorous contractions of the stomach, when the external conductor was placed on a level with, and a little to the left of, the ninth dorsal vertebra. Bocci, 1881, made some experiments with a gastro-electrode in the form of an œsophageal sound for the direct faradization of the internal walls of the stomach, but gave no therapeutic results. In both these instances faradization alone was used, for fear of causing eschars on the mucous membranes of the stomach.

It is evident, however, that the galvanic current would be much more to the purpose. Induced currents are very rapid, of short duration, and act but feebly upon the non-striated muscle fibres, which take time to respond to stimuli. The galvanic current excites the muscles to their maxima, and is alone capable of acting with sufficient energy to arrest the disordered contractions of these muscles.

The electrode used by Dr. Bardet consists of a rubber tube with eyes near one extremity, and a metal T tube fastened to it at the other. To one of the free arms of the metal T, which is at right angles to the œsophageal tube, a second rubber tube is attached. This tube acts as a syphon when fastened to a suitable vessel. The œsophageal tube being passed into the stomach, the electrode is passed down its interior. This electrode is made of a thin ribbon of maillechort terminating in an olive of cornuustum. The length of the electrode is calculated to pass only to the eyes of the sound, so as to insure the fact that the mucous membrane is never in contact with the conductor. A certain quantity of water is then passed through the syphon tube into the stomach, which thereby becomes distended, and the layer of fluid serves to diffuse equally the electric current over the inner surface of the organ.

As to which pole it is best to use, when it is a dilatation of the stomach that is to be treated, the negative pole would be used as producing the most active contractions; when it is vomiting and spasmodic phenomena that are to be combated, the positive pole would be the most useful. Moreover, the interrupted current would be used in dilatation, and the continued current in the other forms.

The intensity of the current in the case in which it was used by Bardet was from 15 to 25 milli-amperes, and continued from five to ten minutes. The pole which is intended to close the circuit may be held in the hand in cases of vomiting, or, in cases of dilatation, may be placed over the epigastrium attached to a broad plate of steel covered with a moist piece of chamois skin.

When the electrode is removed the liquid must also be removed from the syphon before the œsophageal tube is taken away. During the application the patient feels the energetic contractions of the stomach, which may also be felt through the walls of the abdomen on using the hand. The method causes very little pain, and can be readily used on those patients who are accustomed to having the stomach washed out by the syphon tube.

SURGERY.

THE MODES OF PRESERVING SPECIMENS FOR MICROSCOPICAL EXAMINATION.—Prof. Cornil, while complaining (*Archives de Médecine Navale*) that many valuable specimens have been totally ruined, which were sent to him for examination in his pathological laboratory, on account of a want of proper precautions for their preservation, gives some clear rules to guard against these accidents. The reasons why these specimens were spoiled, are as follows: sometimes they were already decomposed when put into a preservative fluid; others were too large for the small amount of the preservative. Valuable spinal cords have been sent twisted up in cork-screw shape in phials containing enough alcohol simply to harden the surface, while the interior softens and decomposes. For a given specimen, the fluid which suits it best should be selected. It is often impossible to examine the most interesting parts of a specimen because a hardening reagent has not been used sufficiently early. Sometimes a brain or cord came which had been for several days or weeks in a very strong solution of chromic acid, the surface was burnt, while the interior was decomposed. Sometimes a tube is sent, supposed to contain a particular kind of bacteria, and collected without any precautions, naturally only the bacteria of putrefaction would be found. Often a big-bellied vessel is sent, with a narrow neck, through which the specimens had to be squeezed, and of course misshapen, to be inserted, and which, being filled with all sorts of specimens, had to be broken to extract them.

1. A specimen is in its best condition when taken from a living body, or as soon as possible after death, and placed immediately in an appropriate liquid. Fresh tissues taken either after an operation or during an autopsy, present a cohesion which is rapidly lost when the blood and other fluids have left them, and the cadaveric decomposition has commenced. So it is necessary to place them at once in a preservative or hardening fluid, particularly if one wishes to study the delicate modifications of the cells, or to search for the pathogenic bacteria.

2. Specimens removed in surgical operations. Portions of the tumor or member removed, should be cut into fragments that are very small in comparison with the amount of liquid into which they are to be placed. The amount of fluid should be generally twenty times as great as the size of the specimen to be placed in it. If it be simply to determine the nature of a fleshy tumor (epithelioma, carcinoma, sarcoma, myxoma, myoma, etc.) the razor or bistoury is used to detach from the centre, and from one or two points on the periphery, two or three cubes of about 1 cubic centimeter in size, washed well in distilled water, if bloody, and placed in alcohol of 80° to 90°, suspended in a vessel that will hold about 50 grs. of alcohol, with a large mouth closed by a ground glass stopper or a metal cover. Instead of suspending the specimens, they may lie upon a bed of tow at the bottom of the vessel. Cork stoppers, besides closing the vessel imperfectly, have the inconvenience of growing a mold upon their inner sur-

face; if it is necessary to use them, dip their lower portions in paraffine and seal them with wax.

To study the indirect multiplication of cells [kario-kinesis] in tumors or alterations of the skin, after selecting a part which is supposed to be in active development, it is placed immediately in absolute alcohol or in a solution of chromic acid 2-1000. Ten minutes or a quarter of an hour after the removal of the tumor would be too late. To separate the elements of a tumor, a fragment of about 2 cubic millimeters should be placed in a vessel of 30 gr., containing 2 parts of distilled water to 1 part of alcohol at 90°. The fluid should be renewed in 24 hours, if the examination is not made.

To preserve all the blood contained in vessels, or in cavernous tissue, as in an angioma, Müller's fluid should be used (20 gr. bichromate of potass., 10 gr. sulph. sod., to a litre of distilled water).

If the tumor is small, the whole of it is put in without opening it, or a lobule, if it is too voluminous. The quantity of liquid used should be twenty times greater than the volume of the specimen. To study nerves taken from a tumor, a sarcoma or myxoma of the nerves, or in the amputation of a limb, etc., a thin shred of nerve, about 1 to 3 centimeters long, should be removed by the scissors, fixed at its two ends and placed in a groove on a small splinter of wood, a match, for example, which is to be inserted in a glass tube containing a 1 per cent. solution of osmic acid. The subcutaneous painful tumors which are supposed to contain nerves, are also put in the same solution of osmic acid, the fragments must be small enough to allow the solution to penetrate into their interior, and should not be more than 2 millimeters thick, and 6 or 7 millimeters long. After remaining 24 hours in five times their volume of osmic acid, they are to be washed with distilled water and put in absolute alcohol.

To preserve the specimens for examination with the naked eye, a temperature of 32° to 46° F. will keep them for several days without change. Otherwise, chloral in solution of 10 p. 100, preserves very well the appearance and color of the parts; the liquid should be renewed if it becomes muddy, and the specimen should be suspended in ten times its own volume of the solution.

Alcohol is the best preservative; to use it properly, the specimen should be washed for 24 hours, in a large vessel where a current is established from the bottom by rubber glass tubing, and then placed in alcohol, so as to be bathed by it at every portion, the dissected or isolated parts to be suspended by threads from glass rods. Another way is to wash the specimen quickly, then place it in half alcohol, half water for two or three days, and then to put it in alcohol of 80° or 90°. The advantage of the alcohol is that it allows of an ulterior microscopic examination, which other liquids do not. But whatever means are employed, the specimen will lose its color and become blanched.

3. To obtain the bacteria from a liquid (purulent discharge from the genital organs, pus, sputa, fluid of cutaneous eruptions, leprosy, variola, etc., liquid of thoracentesis, abdominal punctures, etc.), a very

clean bistoury should be taken, which has been washed in alcohol and heated in a flame, on the point of which a drop of the liquid is taken up and spread upon a thin layer of glass, which has been washed with water and with alcohol and dried with care. This is covered with a similar piece of glass, which has been treated in the same way, and the delicate layer of fluid will dry rapidly, they are then wrapped in paper. They can be kept one or two days before being used. The blood obtained by pricking the finger after a careful washing with soap, and then with alcohol, can be prepared in the same manner, only to preserve the red blood globules, the glass must be exposed for a quarter of an hour in a moist chamber to the vapors of osmic acid. As the urine dries very slowly, owing to the hygrometricity of its salts, a very small quantity should be taken and dried over the lamp flame. The meatus must be washed with care, and the material taken during micturition. With women it is nearly always mixed with the secretion of the vulva and vagina.

Twenty-four or thirty hours after death in summer it is useless to search for bacteria; but if the cadaver has remained at a temperature of 32° to 46° F., at the end of twenty-four hours they can still be found, and prepared as above, in, for example, the fibrinous exudation of serous inflammations, pneumonia, the scrapings of the liver, the kidneys, lymphatic ganglia, the pultaceous fragments or soft vegetations of rheumatismal or ulcerated endocarditis, the pus from the abscesses of internal organs, the contents of tuberculous cavities, of syphilitic gummata, the intestinal fluid, the surface or bases of ulcerations of typhoid fever or dysentery, the contents of the articulations in arthritis, etc. etc.

In looking for bacteria in tissue sections, they should be taken from the living body, as a small portion of the skin or subcutaneous cellulose-adipose tissue detached from the border of an incision made in opening an abscess, or a minute section made with the patient's consent, from a tubercle of leprosy or lupus, or in erysipelas, etc. These fragments of one or two millimetres in thickness by 8 or 10 inches in length, are placed at once in a phial containing alcohol at 90°, which is the best for them, although it contracts them a little and reduces their dimensions.

4. Precautions recommended for certain organs and tissues particularly. *Skin.* As many of the cutaneous eruptions blanch out after death, so as to be no longer recognizable (spots of typhoid fever, erythemata, superficial papules, etc.) it is well to mark them before death, with aniline or nitrate of silver. The parts so marked to be taken as soon as possible and put in alcohol, Müller's fluid, or osmic acid.

Nervous System. Bichromate of ammonia 2-4 p. c., sections to be made carefully. In tuberculous meningitis, two convolutions with the pia mater covering them undisturbed may be placed in alcohol. Very small fragments of the brain and cord may be put in osmic acid to study fatty degeneration.

The reagents mentioned are all useful in preserving the various parts of the body in a simple manner, as to the *Eye*, to preserve the retina, osmic acid should be injected as soon as possible by a fine (Pravaz)

syringe, through the sclerotic into the vitreous humor, twenty-four hours later the globe is to be cut through and placed in distilled water for an hour and then put into alcohol. This can be done after the surgical enucleation of a diseased eye; or it can be placed whole in Müller's solution, taking care first to prick the sclerotic in several places to allow the preservative fluid to penetrate into the interior.

PERFORATING WOUND OF THE HEART.—J. Landborg (*Nordiskt Medicinskt Arkiv*) gives the case of a man 53 years of age who had been an inmate for six years of an asylum while suffering from dementia. During that time he had satisfactory general health and a good appetite, until finally he took to his bed, refused food, but drank a good deal, seemed very weak, but did not complain of anything, perspired excessively, nothing abnormal about the thorax, heart sounds normal, pulse full and regular. He died within three days.

At the autopsy the folds of the pericardium were found to be agglutinated by strong trabecular adhesions. In the muscle fibres of the heart, posteriorly and 1.5 cm—above the apex there was a sail-maker's needle, penetrating through the walls of the left ventricle, with the head entirely within the cavity. It had formed about itself, on the walls of the heart, an infundibuliform opening, circular on the surface, with a diameter of 1 cm. Corresponding with this opening was one in the parietal pericardium, following which a canal was found passing beyond the pericardium and the diaphragm to the left lobe of the liver and the wall of the stomach, these organs were all adherent each to the other. When the parts were in situ and the needle in its original position, its point was free in the stomach; and so closely adherent was it to the tissues, that no fluid could be made to penetrate the intermediate space. In spaces where the point of the needle could reach the opposite side of the stomach, the mucous membrane was slightly scratched with traces of injection. No hæmorrhage. The needle was 9 cm long, triangular, and rusty in its superior portion, a part of the eye of the needle still remained.

OBSTETRICS AND GYNÆCOLOGY.

ON NON-BLENORRHAGIC VAGINITIS.—Dr. Martineau has published his views on this subject at some length, a review of which is to be found in the *Archives de Tocologie*. As to the structure of the vagina, he does not admit the presence of glands, and limits his study to the constitutional and non-constitutional forms of vaginitis. Constitutional vaginitis develops suddenly, or consecutive to an irritation. It may be under the influence of a gouty, scrofulous, herpetic, or dartrous constitution, of which the author has observed about thirty cases. It may exist alone, which is rare, with metritis, or with constitutional vulvitis, which is more common. With herpetic vaginitis generally the cutaneous system is also involved by the same disease.

The secondary constitutional vaginitis is quite frequent, and results from menstruation, pregnancy, labor, metritis, traumatism, masturbation, coitus,

horseback exercise, and the frequent introduction into the vagina of pessaries, injection pipes, etc. The symptoms vary according as the vaginitis is acute or chronic, constitutional or non-constitutional. When acute it commences with a sensation of heat and dryness of the vaginal mucous membrane; then follows a secretion, which passes by degrees from a mucous, colorless character to a white, purulent and even greenish character. The quantity is variable. The secretion is but the product of a simple exudation, an exfoliation of the most superficial layer of the mucous membrane. The microscope shows numerous globules of pus, a considerable quantity of epithelial cells, the *trichomonas vaginalis*, and a certain number of algae and vibriones.

Later, the pain increases and irradiates through the pelvis, the vulva become red and inflamed, but there is no *urethritis*. Finally, there may be inflammation even to suppuration of the perivaginal and inguinal ganglia. The touch, which is painful, encounters the folds of the vagina, prominent, rugous, and covered with granulations. The speculum when introduced causes a slight bleeding from the inflamed surfaces, and passes in with some little difficulty. It exposes the intense redness of the mucous membrane, which is covered by a layer of pus. The cervix uteri partakes of the inflammation, and presents erosions, which, however, do not pass into the interior of the neck. The granulations are due to an hypertrophy of the normal papillæ, and not to any glands. Constitutional vaginitis, on the other hand, is rarely acute, and Dr. Martineau recognizes several varieties:

1. Scrofulous vaginitis, which may or not be granular. It is characterized by a discharge that is rather sero-purulent than purulent, and by the presence of disseminated small vesicles, situated either lineally on one or all parts of the walls (herpes), or grouped in small patches which are slightly prominent and irregular in form (eczema), not confined to the vagina, but also present on the cervix uteri.

2. Arthritic vaginitis, which is characterized by an intense redness, almost the color of urine lees, of the vaginal mucous membrane. Its progress is irregular, its duration prolonged, it is subject to relapses, which seem to be dependent upon the variations of temperature, the humidity of the atmosphere, and sudden cold. It is coincident with other evidences of arthriticism, as muscular and articular pains, neuralgia, etc.

3. Dartrous vaginitis. This is accompanied by vulvar-lumbo-abdominal neuralgia and crural neuralgia, the vulvar hyperæsthesia may become true vulvism with contraction. (?) The herpetic and eczematous eruptions are numerous, and are generalized on the vulva, vagina and cervix uteri. They coincide with morbid manifestations of the same nature, either on the external integument or in connection with the viscera.

The diagnosis comprises the diagnosis of the lesion, or anatomical diagnosis, of the cause or pathogenic diagnosis, and of the nature of the affection or nosological diagnosis.

Dr. Martineau insists particularly on the different characters of the discharges from the vagina, uterus and vulva.

THE
Journal of the American Medical Association.

PUBLISHED WEEKLY.

THE EDITOR of this JOURNAL would be glad to receive any items of general interest in regard to local events, or matters that it is desirable to call to the attention of the profession. Letters written for publication or containing items of information, should be accompanied by the writer's full name and address, although not necessarily to be published. All communications in regard to editorial work should be addressed to the Editor.

SUBSCRIPTION PRICE, INCLUDING POSTAGE.

PER ANNUM, IN ADVANCE..... \$5.00.

SINGLE COPIES..... 10 CENTS.

Subscriptions may begin at any date. The safest mode of remittance is by bank check or postal money order, drawn to the order of the undersigned. When neither is accessible, remittances may be made at the risk of the publishers, by forwarding in REGISTERED letters.

CHICAGO, ILLINOIS.

SATURDAY, AUGUST 23, 1884.

TREATMENT OF EPIDEMIC CHOLERA BY LARGE HYPODERMIC INJECTIONS OR INFILTRATIONS.—A few weeks since we published a brief communication from Dr. S. S. Todd, of Kansas City, Missouri, proposing to treat cases of epidemic cholera largely by injections of considerable quantities of whisky and water into the subcutaneous areolar tissues, with the expectation that it would be taken up fast enough to prevent the blood from becoming too much exhausted of its water and saline elements by the copious gastric and intestinal evacuations which accompany the active stage of the disease.

In the present number we give place to a letter from Dr. Uhler, of Baltimore, touching the same subject. He commends the object sought to be accomplished by Dr. Todd, but thinks that the direct injection, by large hypodermic syringe, of sufficient fluid for the purpose, would rupture the subcutaneous areolar tissue and lead to extensive suppuration. To obviate this he suggests a method by which the fluid could be more slowly and continuously introduced into the tissues or directly into the cavity of the peritonæum, from which it would be rapidly absorbed by the peritoneal membrane.

All these suggestions are founded on the assumption that the chief danger from cholera is in the loss of the water and salts of the blood, leaving that fluid too viscid to circulate; and that a supply of these elements as fast as they are lost would result in curing the disease.

Our own clinical experience with cholera, suggests that there would be much practical difficulty in car-

rying out the propositions of either Drs. Todd or Uhler. To inject hypodermically from 60 to 120 cubic centimeters (fl. ʒii to ʒiv) of any kind of liquid directly into the areolar tissue of an extremity, and repeat it often enough to make any adequate offset to the quantity being discharged from the mucous membranes in the active stage of cholera, would necessarily rupture and disorganize that tissue, as stated by Dr. Uhler. And to keep four or more hypodermic syringe points constantly inserted and connected by rubber tubing with a fountain containing the liquid to be infiltrated into the tissue, as proposed by Dr. Uhler, while the patient is vomiting, purging, and writhing under the muscular cramps every five or ten minutes, would require more fortitude and patience in preserving one position, than I have ever seen in persons in the active stage of this disease.

If we wait until the patient gets quiet enough to keep Dr. Uhler's apparatus adjusted, continuously, it will be when he is in so profound a collapse that the capillaries will fail to take up the infiltrated liquid. What effect the injection of water, or medicated water, into the peritoneal cavity during the progress of a case of cholera, would have, can be determined only by trial. We apprehend, however, that all these expedients, even if carried into practical effect, would lead to the same result as has been found to follow the direct injection of various diluent liquids into the veins, namely, a temporary improvement of the circulation, followed shortly by renewal of intestinal discharges and return of the collapse. The truth is, that the rapid drainage of the serous fluids of the blood and tissues is simply an *effect* resulting from the inversion of the natural action of the mucous membrane of the alimentary canal; and until this inverted action is reversed, the mere supply of water or any artificial serum, whether it be by hypodermic infiltrations, venous injections, or injections into the peritoneal cavity, will only furnish additional material for discharges, without otherwise altering the progress or final termination of the case.

MORPHINE IN THE EARLY STAGES OF INSANITY.—The responsibility of the physician in the use of morphia, in consequence of the possible development of the morphia habit, is great; but his responsibility relative to the possible disaster of a preventable lifelong insanity, not prevented, is, if possible, still greater.

Auguste Voisin,¹ of the *Salpêtrière*, Paris, claims

¹ *Lçons Clinique sur les Maladies Mentales*, etc., Paris, 1883.

for the use of the hydrochlorate of morphia, in gradually increased large doses long maintained, remarkable results in the treatment of certain forms of insanity. His theories are well sustained by physiological observations, and his cases are taken from the records of the *Salpêtrière* and private practice, and many of the cases have been examined after the lapse of several years.

In the article referred to, "Leçon Trentième," he gives a resumé of the history of the systematic use of opium and morphia in the treatment of insanity, and dates his own experience with it from the year 1867. His success was at first greatly diminished by the obstinate vomiting which frequently occurs; but on learning from M. Roller, Physician of the Insane Asylum at Illenau, France, that, regardless of the vomiting, the dose should be increased, he continued to increase the dose, and to that instruction he attributes his success. He has since treated successfully the various manifestations of insanity which would seem to correspond practically to the first division adopted by the International Congress of Alienists in 1867, namely: simple insanity, comprehending mania, melancholia, monomania, circular insanity, moral insanity, in their early manifestations.

He uses exclusively the hydrochlorate of morphia, and only hypodermically, but fails to give the strength of the solution which he finds most satisfactory. He does not mention the combination, so much appreciated in America, of morphia and atropia. Probably the association of the atropia is not to be desired. He speaks against the tablets in use, and especially objects to warm water as a vehicle. The efficacious dose desirable to sustain until the desired effect is obtained, can only be found by proceeding cautiously and studying each individual apart. One rule which the author never departs from, is not to exceed, in the initial dose, from one to three milligrammes. Whilst light cases associated with hallucinations are frequently relieved in a few days with a daily dose of from five to six centigrammes, yet in other cases the dose has to be increased to seventy centigrammes. He narrates one case in which two grammes of the hydrochlorate of morphia, in two doses, were administered daily, with no manifestation of its presence beyond a contraction of the pupils. The latter was one of the unsuccessful cases. He never entrusts the administration to a nurse.

The influence of the medicine exhibits itself in the order of their appearance by a redness of the face and conjunctivæ, nausea, vomiting, general sensation of heat, lassitude, sleep, loss of weight, dimi-

nution of arterial tension; later, an improvement of the countenance is manifest, the face becomes more intelligent and the tint of the flesh improves, the general weight now increases, and in women, the courses reappear. The manifestation of any of these symptoms supports a favorable prognosis, whilst their absence is unfavorable. Where there is great emaciation, previous to the commencement of the morphine treatment the author practices transfusion. The presence of a congested condition of the cerebro-spinal system he considers an absolute contra-indication for the use of morphia. Consequently in some cases he first applies blisters to the nape of the neck or other convenient regions, and regards its use as absolutely contra-indicated in epilepsy, general paralysis, and insanity due to an atheromatous condition of the arteries.

He mentions three phenomena which he considers of importance in pronouncing an opinion relative to the cure of the patient: The consciousness of their former condition, the recollection of their delirium, and a sense of gratitude towards those from whom the relief was obtained.

Judging from a purely theoretical point of view we should say that the plan of treatment is eminently philosophic. It is not at all unreasonable to suppose that many such cases may arise from an exaggerated form of ordinary sadness, suspicion, or diluted but universal pain, associated it may be with a condition of body incapable of throwing off the superimposed incubus. Let us suppose, for instance, that the pain associated with a severe felon, a toothache or earache, instead of being confined to one place, disseminated over the whole body so that the sufferer cannot locate his seat of pain; the pain would not necessarily be the less because it was thus distributed, the patient would, however, be very much less likely to obtain relief from the physician; and we have only to suppose that general feeling increased and unrelieved to disturb the equilibrium of the best of us. If, as we are led to suppose by Auguste Voisin, the arterial tension is constantly increased in the initial stages of insanity, it would not be unreasonable to suppose that in such cases some such universal agent is at work, and from our experience with morphia as a magic power in the relief of other affections of a painful, ease-disturbing nature, we ought to expect it to be equally efficient, at any rate in certain cases of insanity, arising apparently from an ill-defined but universal pain, whether physical or moral.

Such a method of treatment offers special advantages in the possibility of saving a patient from being sent to a retreat, which is sufficient in itself, in many

cases, to develop a spirit of resentment which would add to the chances of a relapse. As to the possibility of developing the morphia habit, it would be very injudicious to ignore it; but in urgent cases risks have to be taken, and by following the example of Auguste Voisin in allowing the remedy to be administered by the physician alone, the danger is reduced to a minimum.

PROGRESS OF CHOLERA IN EUROPE.—While the epidemic in Toulon and Marseilles is diminishing, apparently for want of material to feed it, it is steadily extending to other parts. A dispatch of the 16th inst. says:

"There are now forty-one places and thirteen departments in France from which deaths from the cholera have been reported, and there are doubtless half as many more towns and villages from which no reports have reached the world outside. The cholera area now stretches from Toulouse, in the southwest, to Auxerre, in the north, in the department of Yonne, and to the gap in the southeast in the Haute Alps, thus making a triangle whose sides are respectively 235, 245, and 310 miles long. Auxerre is only about 100 miles from Paris in a southerly direction."

It also exists in many places in northern Italy, and in the Nostras prison at Geneva, Switzerland.

What is called *English Cholera*, has been for some time prevailing with considerable severity in Northampton and neighboring villages, in England.

INTERNATIONAL MEDICAL CONGRESS AT COPENHAGEN.—This body closed its session according to programme on the 16th inst. The number of members present is stated at about 1,600, of whom about fifty were from this country.

SUPPOSED DUPLICATES OF JULY 19, 1884.—If there are any of our readers who still think they have received *two* copies of the JOURNAL for July 19, Vol. III, No. 3, and no copy for July 26, Vol. III, No. 4, let them compare the supposed duplicate numbers by examining the date and number at the top of the first inside page of reading matter, as well as the contents of the two copies, and they will find that they have both numbers *three* and *four*, the latter only being wrongly dated and numbered on the front outside page.

INTERNATIONAL MEDICAL CONGRESS.—A dispatch from Copenhagen of the 13th inst., stated that Dr. J. S. Billings, of U. S. A., and delegate from the American Medical Association, had presented to the Congress there assembled an invitation to hold the next triennial session in this country in 1887. If the invitation is accepted, those who attend will meet a cordial reception from the profession in this country.

SOCIETY PROCEEDINGS.

GYNÆCOLOGICAL SOCIETY OF BOSTON, MASS.

The Society met for its regular February meeting, H. O. Marcy, M.D., President, in the chair, and H. G. Harriman, M.D., Assistant Secretary.

Dr. Marcy again thanked the Society for the recent honor of his unanimous election to the chair. He realized the responsibilities of the position, but had concluded to accept it, although full of zeal for the greatest good of the Society, because he believed, after all, that the effective work must still be done by the "rank and file." In the year to come he would use his efforts to advance every interest of the organization, and render it an aggressive force both at home and abroad.

Frank S. Billings, M.D., associate member, then read the paper of the day, upon "Eclampsia Parturientium in Woman and in the Cow," of which a digest follows:

As respects etiology, eclampsia is the most theoretical of all diseases. Derivatively speaking, the term is applicable to but a single one of the many phenomena which it is made to cover. Usage has also restricted its application to such phenomena occurring in woman during the *puerperium*; but, in reality, it equally applies to similar conditions occurring in scarlatina, diphtheria, etc. Convulsions in parturition would be a better designation than eclampsia.

Eclampsia is not a disease; rather it is a symptom of a diseased condition of the organism. It represents a result, the outward visible phenomena by which certain internal disturbances manifest themselves to the observer.

Definition.—Other medical men agree more fully regarding the nature of the disease than do veterinarians. Frank alone, among veterinary writers, looks upon the accident commonly called milk fever, calving fever, collapse, etc., as identical with eclampsia in woman. He defines to the following effect: An acute and very dangerous disease in cows, especially common in the great milk-producing breeds, characterized by unconsciousness, paralysis, and sometimes convulsions, due to uræmia of the brain.

The reason why convulsions are not so frequent and so severe in the cow as in woman, is that the degree of nervous irritability in the bovine species is much lower.

Eclampsia in woman Spiegelberg defines as epileptoid convulsions of a tonic, or, more especially, of a clonic character, which appear during the puerperium, accompanied by unconsciousness and coma. Nothnagel regards it as an acute epilepsy. Wernich connects it with injury done to the ischiatic nerve, by the uterus, which produces excitability to the pons and the medulla oblongata. If to this assumed injury be added irritation of the nerves of the general system, eclampsia results.

The reader next gave a full exposition of the cause and phenomena of this disease, in woman and in the cow, of which the following is a brief *resumé*:

In woman the affection is essentially one of parturition, but it may occur in other diseases. Eclampsia in animals is almost entirely limited to parturition—being even more restricted than in woman—but seldom occurs even then in other animals than the cow. Prodromal phenomena are present in woman, and probably also in animals. Amaurosis is a constant attendant in both; œdema of face and extremities present in woman, but not in animals; convulsions frequent in woman, infrequent in animals; pulse and respiration similarly affected in both; temperature increased in woman, decreased in animals; bladder contains little urine in both. Secretion of milk either diminishes or ceases altogether in animals; nothing reported in regard to woman. In animals we find complete paralysis of digestive tract, cessation of defecation, and dessication of the fæces. Tympanitis present in cows.

Etiology.—The only two theories worthy our present recognition are, 1st, the Traube-Rosenberg theory, to the effect that eclampsia is due to œdema cerebri and the sequential anæmia; 2nd, that it is due to intoxication of the blood with the entire elements of the organism which go to make up the urine.

Objections to the T.-R. theory are numerous. Convulsions occurring in scarlatina, diphtheria, etc., are *not* due to œdema cerebri, but *are* due to nephritis and to consequent retention of elements in the blood. Still, all cases of nephritis and retention of elements of urine in the blood are not followed by eclampsia; therefore an unknown something must be involved in the production of the disease besides urine-intoxication. This something may be prolonged action on the nervous elements, or sudden and intense action. According to the urine-intoxication theory, the blood-intoxication is not due to retention of urates alone, but of all the elements of the urine. The semi-paralyzed condition of the muscles of respiration doubtless aids this toxic influence of the urine by interfering with the oxidation of the blood.

Spiegelberg, Cohnheim, *et cet.*, were quoted in support of this latter theory.

There are many predisposing and supporting circumstances connected with the procurement of eclampsia in the cow. Nephritis, which is so frequent an antecedent in woman, is not often present in the cow.

The disease is always associated with a quick and easy parturition, and the contraction of the uterus is speedy and prompt. Eclampsia seldom comes on before the delivery of the secundines.

It appears to belong especially to the great milk-producing breeds, and is, essentially, a product of refinement in breeding. Over-feeding and an over-fat condition of fine-bred cows predisposes to the evil. It seldom occurs during the first or second parturition, and diminishes in frequency after the seventh or eighth; it therefore appears most frequently at the height of milk production.

In conclusion, the reader gave his own opinion respecting the etiology of the disease in effect as follows: Eclampsia parturientium is due, 1st, to a peculiar irritability of the uterine plexus, producing a neurosis which acts, 2nd, upon the arterial circula-

tion, especially in the kidneys, causing retention of urine-elements in the blood and tissues; to which may be added the statement that anæmia cerebri may be due to the same reflex irritation which causes contraction of the renal arterioles.

After the reading of the paper, the chair suggested that the discussion which was to follow might very profitably be directed towards the treatment of eclampsia, as the reader, from lack of time, had not considered this department of the subject.

In reply to question, Dr. Billings said he did not know whether paralysis of the bowels existed in women as it does in cows. Cows are purged at once, and other efforts made at elimination.

Dr. Warner asked if cessation of defecation was due to paralysis or to spasm. Reply—It is certainly due to paralysis.

Dr. M. L. Brown thought purging was striking at an effect rather than at a cause, and that something calculated to allay nervous irritability, chloral hydr., e. g., would be better. Morph. sulph., in large doses, (gr. ss., gr. ij.) would fill the same indication. Army service taught him that pressure on both carotids would sometimes control convulsions.

Dr. Billings, in reply to question, said that chloral hydr. was not used with cows. Physostigmine, (8–10 grs.) had been used, in conjunction with enemata, hot blankets, etc. Blood-letting has been abandoned.

Dr. Wheeler had not noticed cessation of milk in woman, as patient is either dead or relieved before milk appears. Neither had he observed arrest of defecation in woman, but was accustomed to purge both in order to eliminate and deplete.

Dr. Grainger had not observed intestinal paralysis in woman, and thought it would have been noticed if it were present.

Dr. Billings rejoined that stagnation of peristalsis in cattle came on suddenly. The last operation of the bowels previous to eclampsia may have been normal; as soon as the attack supervenes, the bowels are wholly paralyzed and the fæces rapidly become dessicated.

Dr. Grainger would not trust to chloral hydr., had tried it and failed. Had successfully tried venesection, with pilocarpin hypodermically.

Dr. Billings believed venesection to be generally of little value; if used at all it should be resorted to in the beginning of the attack, and should bleed freely.

Dr. Marcy had used pilocarpin with varying success, but was not satisfied with it. In his last case, had found fatty degeneration of capillaries of kidneys. Venesection was advisable in certain cases. Had lately seen a case where a history of albuminuria for several months was followed by normal labor.

Dr. Wheeler thought we should recognize two types of the disease, and these should receive different treatment. One, the sthenic, found in patients who are strong, full-blooded and robust, with tendency to apoplectic symptoms. The other type is presented by the anæmic and nervous. In the former class, venesection should be used, followed by morphia or ether; with the latter, venesection is contraindicated, and ether, morphia, etc., must be our chief depend-

ence. In reply to a question of Dr. Horace White, Dr. Wheeler farther said he did not think pilocarpin would deplete quickly enough in some cases, in which venesection, quite likely, would work much better.

Dr. Grainger mentioned a case of albuminuria where the urine was nearly solid on boiling, patient had moreover spots before the eyes, ringing in the ears, etc., etc. The labor was normal. Venesection in proper cases should be resorted to very early, and the patient bled rapidly, in sitting posture, so as to affect the brain at once.

Dr. Church thought the presence of albumen not particularly dangerous if the amount of urine be not diminished; if, however, the urine be both scanty and albuminous, labor should be induced.

Dr. M. L. Brown had used veratrum viride with good results. As soon as the pulse reached the normal, convulsions ceased, though in one case delivery did not take place till 24 hours afterwards. But veratrum viride is not applicable to all cases, as it is not rapid enough in its action.

Dr. Wheeler had found the uterus firmly contracted after delivery in cases complicated with eclampsia. Dr. Billings did not know of any epidemic form of the disease among animals.

Jas. R. McLaughlin, V.S., of Newton, being present by invitation, was asked by the Chair to give the results of his observation upon the subject before the Society. The doctor replied that the veterinarian generally labored under the disadvantage of being called to the case late, and after the animal had been down some hours. His chief effort in treatment was in the direction of elimination, and this by the bowels, which were, of all organs, the most susceptible to impression in the cow. Gave strong cathartics, as a very positive form of constipation is always present; also employed hot applications to the loins, in neighborhood of kidneys—cloths wrung out of hot water and confined with rubber cloth to prevent evaporation, also frequently gave warm ale, in Oss. doses, repeated every four hours. The majority of cases die, and when recovery does take place, it is a question with many of the profession whether the actual disease were present, and not rather a hysterical sophistication of it. In one case with favorable issue, the animal had right afterwards a well-marked case of pneumonia, but finally recovered from this also. She was a rich milker—milk like cream. A year previous to the seizure, he had treated her for œdematous swellings all over the pendent portions of the body, legs, udder, etc.; when she came to have her first calf it was complicated by the experience just related.

The doctor further remarked he had made a number of post-mortems but never found anything calculated to throw light either on the nature of the disease or its treatment. Confinement in cellars seems to predispose to eclampsia; had lately been consulted in case of a valuable cow owned by a wealthy family, which had had successive seizures on occasions of previous calvings; advised to remove her from the cellar in which she was kept, and to build a proper barn. Also pursued depletory measures, ordered a regulation of exercise, and when she came to have her calf all

proceeded well and without complication. "The poor man's cow," added Dr. M., "like the poor man's wife, generally gets on well and escapes the disease."

At the close of the discussion, Dr. Billings called attention to, and presented sample copies of, the "*Journ. of Compar. Medicine and Surgery*," of which he is one of the editors. The doctor also recommended a soap consisting of Bals. Peru 20 per cent. powd. Castile soap, 8 per cent., as having proved effectual in the relief of eczema, dandruff, leucorrhœa; also effective in removing offensive odors from the hands. Great difficulty is experienced in making these ingredients unite, but it can be accomplished. Dr. B. recommended the following for the disguise of the smell of iodoform:

R Iodoform.....gr. ci.
Acid Carbolicgr. ij.
Ol. Ment. Pipgtt. v—x.

Society adjourned.

CHICAGO MEDICAL SOCIETY.

Regular meeting August 4, 1884, Dr. D. A. K. Steele, President, in the chair, and Dr. L. H. Montgomery, Secretary. After the preliminary business, the remainder of the evening was occupied in the consideration of epidemic cholera. Dr. J. H. Etheridge read a brief paper enumerating the various remedies that had been proposed and used in the several cholera epidemics of the past 60 years. He did not discuss the *modus operandi* or the therapeutic value of any of the remedies, but simply gave a catalogue of such as had been suggested and used to some extent during each successive epidemic. The list embraced nearly 130 articles, among which were some of the most active in the materia medica, as calomel, opium, venesection, cathartics and emetics, and many that were entirely inert. He was followed by Dr. I. N. Danforth, who gave an interesting account of the pathological changes or morbid anatomy of cholera patients, illustrated by micro-photographic representations of the mucous membrane of the ilium as shown by post-mortem examination of persons dying of cholera in 1873; also, similar illustrations of the constituents of the matters vomited and passed from the bowels before death. His examinations showed the uniform presence of three pathological conditions as the result of fatal attacks of epidemic cholera, *i. e.*, great loss of the water and saline constituents of the blood, leaving it too thick to circulate freely through the capillaries and smaller vessels; an abundance of epithelium cells and several varieties of microbes in the intestinal evacuations; and extensive denudation of the villi and other parts of the mucous membrane from the detachment of the epithelium during the active stage of the disease. In nearly all the cases, the cortical structure of the kidney was also much congested, and the secretion of urine scanty or suppressed.

Dr. W. T. Belfield gave a brief account of the investigations of Dr. Koch in regard to the cholera bacillus. He regards it as not yet demonstrated that

said bacillus is the efficient cause of the cholera pestilence.

The discussion was continued by Dr. John Bartlett, who had in former years devoted much time to the investigation of the organic germs or fungi supposed to constitute the active constituent of malaria; Dr. C. G. Smith, Dr. C. W. Earle, and Dr. N. S. Davis. The latter, in addition to some reminiscences of the several cholera epidemics in this city from 1849 to the present time, gave briefly his views of the pathology and the method of treatment he had found most efficient in controlling the progress of the disease. At a late hour the society adjourned, with the intention of resuming the discussion at the next regular meeting.

MASSACHUSETTS MEDICAL SOCIETY.—PROCEEDINGS OF THE SUFFOLK DISTRICT MEDICAL SOCIETY.—ADJOURNED SPECIAL MEETING.

Section for Clinical Medicine, Pathology, and Hygiene.

ALBERT N. BLODGETT, M.D., SECRETARY.

(Concluded.)

The enormous dilution of sewage in this country is mentioned as an objection. By analyses the amount of organic matter in the sewage of American and European cities varies but a trifle. Boston consumes more water per capita than Paris. But the latter city dilutes her sewage equal to that of our own by a lavish use of water in washing the streets each morning. And the estimate of three barrels of water to the discharge of one individual here does not include the organic matter constantly discharged from sink drains or the street washings. Durand-Claye, the celebrated French engineer, to whom the world owes a debt of gratitude for demonstrating the possibility of eputation by this method, says, "It is desirable and necessary that there should be a great dilution by water in order to insure rapid transit."¹

The soil does not clog where systematic irrigation is practiced. The thin skin of impervious deposit, when dried, shrinks, cracks, and breaks up, the organic matter decays, and the soil is more pervious than where irrigation is not employed. Reservoirs of deposit are used to eliminate the coarse particles, as their decay on the surface would cause an offensive odor.

It is highly probable that the failure mentioned as resulting from an impervious deposit where "sewage was pumped on a garden," was due to puddling. And that it is an unnecessary accompaniment to irrigation is proved by the employment of this system at Buntzlau on fifteen hectares for over two and a half centuries, and at Edinburgh for over two centuries, without diminishing the permeability of the soil.

As to the impossibility of obtaining suitable soil of sufficient area in Massachusetts for the general employment of this system, the success which has attended the efforts of the English in finding it in their

thickly populated island is an answer. Our forests could be utilized with little expense, and next to Italian rye grass the trees would prove the best absorbers of filth. A few acres of willows at Windsor take care of the sewage of twelve thousand people.

I recall but one other objection, the comparatively large rain-fall here, forty and fifty inches per year. At Gennevilliers 312 inches of water is sent on the land each year, and this "without making it damp or marshy since the establishment of subsoil drainage." And I know of two farms in my native town, in Worcester County, where irrigation with brook water has been practiced with advantage. Our average rain-fall is a little larger than that of Great Britain, where it is from forty to fifty inches per annum, but the yearly average humidity (between eighty and eighty-six) is nearer the point of saturation there than here, where it is about seventy. Dr. Frankland considers the vapor in the atmosphere of England as "reducing the temperature from fifteen to twenty-five degrees;" and Tyndall remarks that "the abundance of atmospheric vapor hinders the radiation of heat at night in England." The protracted droughts which are so common in this country are unknown in England, where vegetation never suffers from want of moisture. I am indebted to Dr. Bullard for facts and figures on this branch of the question, which enable me to say with positiveness that the meteorological conditions of our climate, with the possible exception of winter temperature, are far superior to those of England for the employment of irrigation and agriculture.

To-day I only ask that before building a metropolitan sewer for the eastern part of the State to discharge in tide-water, and thus repeat the now demonstrated errors of London, Brighton, and Torquay, irrigation and agriculture may be tried, on a limited scale, by some one having faith in the success, as we might ultimately desire to reverse the current of the sewage of the metropolitan district.

A large proportion of our rural population have gardens attached to their houses. I would discourage the use of cess-pools and recommend the use of these lands for the disposal of sink water. I am informed that Dr. Jewett, of Northborough, has for many years employed this system, and I have practiced it myself for ten years with complete satisfaction.¹

Victor Hugo, in *Les Misérables*, describing the sewerage of Paris more than twenty years ago, makes a vivid picture of our systems at the present time. He writes as follows:—

"*The Earth Impoverished by the Sea.* Paris throws twenty-five millions a year into the sea. And this without metaphor. How, and in what manner? Day and night. With what object? Without any object. With what thought? Without thinking. For what return? For nothing. By means of what organ? By means of its intestine. What is its intestine? Its sewer. * * * Science, after long experiment,

¹Babot du Maris quotes Dr. Carpenter as saying "the more dilute the better."

¹In view of the well-known results of chemical analyses of sewage the question as to its fertilizing properties seems to be out of place. It is almost the only fertilizer the Chinese employ. "The Duke of Portland used nothing but sewage on his farm at Mansfield, and obtained a net return of about \$125 per acre." (Babot du Maris.)

now knows that the most fertilizing and the most effective of manures is that of man. The Chinese, we must say to our shame, knew it before us. No Chinese peasant, Eckeberg tells us, goes to the city without carrying back, at the two ends of his bamboo, two buckets full of what we call filth. Thanks to human fertilization, the earth in China is still as young as in the days of Abraham. Chinese wheat yields a hundred and twenty fold. There is no guano comparable in fertility to the detritus of a capital. A great city is the most powerful of stercoraries. To employ the city to enrich the plains would be a sure success. If our gold is filth, on the other hand our filth is gold. What is done with this filth, gold? It is swept into the abyss. We fit our convoys of ships, at great expense, to gather up at the south pole the droppings of petrels and penguins, and the incalculable elements of wealth which we have under our own hands we send to the sea. All the human and animal manure which the world loses, restored to the land instead of being thrown into the water, would suffice to nourish the world.

"These heaps of garbage at the corners of the stone blocks, these tumbrils of mire jolting through the streets at night, these horrid scavengers' carts, these fetid streams of subterranean slime which the pavement hides from you, do you know what all this is? It is the flowering meadow, it is the green grass. It is marjoram and thyme and sage, it is game, it is cattle, it is the satisfied low of huge oxen at evening, it is perfumed hay, it is golden corn, it is bread on your table, it is warm blood in your veins, it is health, it is joy, it is life. * * *

"Statistics show that France alone makes a liquidation of a hundred million every year into the Atlantic Ocean from the mouths of her rivers. The cleverness of man is such that he prefers to throw this hundred million into the gutter. It is the very substance of the people which is carried away, here drop by drop, there in floods by the wretched vomiting of our sewers into the rivers, and the gigantic collection of our rivers into the ocean. Each hic-cough of our cloaca costs us a thousand francs. From this follow two results: The land impoverished and the water infected. Hunger rising from the furrow, and disease arising from the river. * * *

"A system of elementary drainage, as simple as the lungs of a man, and which is already in full operation in several villages in England, would suffice to bring into our cities the pure water of the fields, and send back into our fields the rich water of the cities, and this easy see-saw, the simplest in the world, would retain in our possession the hundred million thrown away.

"The present system does harm in endeavoring to do good. The intention is laudable, the result deplorable."

On motion of Dr. Henry I. BOWDITCH, it was

Voted, "That the thanks of this Society be tendered to the scientific gentlemen, not members of our body, who have contributed so much to our instruction and to the great interest of these meetings."

Adjourned.

DOMESTIC CORRESPONDENCE.

THE RATIONAL TREATMENT OF ASIATIC CHOLERA.

BY J. R. UHLER, M.D., BALTIMORE, MARYLAND.

In an article upon Asiatic Cholera, printed in this journal Aug. 9, among other things, hypodermic injections of water, or artificial serum, into the areolar tissue, are suggested in quantity sufficient to supply the waste from the bowels. This I think useful treatment, but the method of applying it does not seem to be the best, since the quantity of fluid needed would, if used in a few places, distend the tissues under the skin to such an extent as to produce large cavities, abscesses, and much discomfort, and if only a small quantity were injected in each place so many punctures would be required as to render it highly objectionable to most patients. A better plan, it seems to me (which I employed to nourish a patient who could not swallow), would be to use two or four hypodermic syringes deprived of their pistons connected by soft rubber tubing, with a reservoir or reservoirs similar to the aspirator, without valves or with valves reversed, containing the fluid, and insert the needles in the loose areolar tissues of each of the extremities and let them remain. By this means the tissues will be continually bathed with the serum filling the tubes by natural flow, care being taken not to elevate the reservoirs too high, so as to produce much pressure, and the liquid could then be uninterruptedly absorbed from the four points.

Another plan which, from doing all the work at once, and from the situation where it is applied, seems preferable to a surgeon, is to inject, and gently fill, the *peritoneal cavity* (by the aspirator or other instruments) with sterilized, artificial serum at the temperature of the body, thus bringing the fluid in contact, like ascitic fluid, with the other side of the greedy intestines, where it will act by pressure, slightly diminishing the lumen of the bowels, and can be absorbed to prevent the tarry condition of the blood, and also by exosmosis dilute, and wash away when the bowels are moved, those low forms of life that are said by Koch to be the cause of the disease.

234 W. Fayette St.

TÆNIA SAGINATI.

CHICAGO, August 11, 1884.

The youngest on record—not the worm, but the patient having it. It is not that tænia is a rare bird, or the catching of it a matter requiring much skill, yet because of the "early youth" of the patient I give you the facts. Ella May Sullivan, of Chicago, born December, 1881—consequently 2½ years old—latterly passed sections of the saginati. On Saturday was relieved of the "varmint." Who can give dates of a younger child passing tænia? Look up your records.

J. R. WILKINS, M.D.

NECROLOGY.

GRIFFITHS, THOMAS JONES, M.D., Surgeon U. S. Marine Hospital Service (retired), was born in South Wales, Sept. 10, 1826: died at his residence in Louisville, Ky., June 1, 1884. He received his literary education in England, and at an early age came to this country and settled at Louisville, Ky., where he studied medicine and was graduated in the Kentucky School of Medicine in 1852. He commenced the practice of medicine in Louisville, and rapidly acquired prominence in the profession, the esteem of his confrères, professional success and prosperity. During the war between the States he was appointed by the government Surgeon in charge of the Park Barracks and several military hospitals in Louisville.

In 1869 he was appointed Surgeon in charge of the U. S. Marine Hospital at Louisville, and remained in this service until 1877, when he retired from active duty on account of ill health, but was made consulting surgeon to the hospital. As an officer of this service he was active, efficient, widely known, and universally popular with his patients.

He was a man of vigorous mental and physical powers, an acute observer, a careful student, and an untiring worker in the line of legitimate medicine, to which he had contributed many valuable papers. He was a member of the various local medical societies in Louisville, the Kentucky State Medical Society, and of the American Medical Association, since 1874.

On the announcement or his death a meeting of the physicians of Louisville was called in respect to his memory, and resolutions of sympathy and regret were passed, which were ordered published in the Louisville and Philadelphia medical journals, also the daily papers.

A large number of physicians of the city attended the funeral, the cortege being one of the largest seen in the city. The remains were interred in Cave Hill Cemetery.

His wife and an only son, Dr. Wm. M. Griffiths, survive him.

H. W. AUSTIN, M.D.

MISCELLANEOUS.

OFFICIAL NOTICE.

ANNUAL DUES from members of the Association—*Five Dollars* per annum—are payable directly to the Treasurer. Such payment entitles them to receive the JOURNAL of the Association for one year.

SUBSCRIPTIONS TO THE JOURNAL from those who are not members should be forwarded to the office of publication, Chicago.

BACK VOLUMES OF THE TRANSACTIONS may be procured, at reduced rates, by addressing the Treasurer.

THE INDEX to the 33 Volumes of Transactions will be forwarded, postpaid, on receipt of *One Dollar* by the Treasurer.

According to a resolution passed May 9, 1884, at

the Washington meeting, continuous payment of Annual Dues is required, to retain permanent membership.

RICHARD J. DUNGLISON, M.D.,
Treasurer.

Lock Box 1274, Philadelphia, Pa.

THE PLAGUE COMING THIS WAY.—Washington, Aug. 19.—The United States consul at Barbadoes, West Indies, telegraphes to the state department as follows: "The ship Bracadaile left St. Lucia for New York on the 16th with cholera. This is the British steamer which left Calcutta on the 4th of June bound for Demerara and New York. The cholera broke out during her passage, and on her arrival at Table bay, July 4, she was reported to have had eighteen fatal cases. There were 651 coolies on board, of whom twenty-eight were down with cholera. The steamer took in coal at Table bay and left for St. Lucia, where she arrived on the 3d inst., and was placed in quarantine." The health officer at New York has been notified to quarantine the vessel on her arrival.

YELLOW FEVER.—The schooner "J. Taylor," from Porto Bello, arrived at Cape Charles quarantine station on the 12th inst., with three cases of supposed yellow fever on board. One death had occurred on board previous to the arrival of the ship. The sick were removed to the U. S. Quarantine Station, Fisherman's Island, and the vessel permitted to proceed to the Baltimore quarantine.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT UNITED STATES ARMY, FROM AUGUST 9, 1884, TO AUGUST 15, 1884.

Bartholf, J. C., Captain and Assistant Surgeon, relieved from duty at Vancouver Bks., Wash. T., and ordered to take station at Portland, Oregon. (Par. 1, S. O., 114 Hdqrs. D. of Col., August 1, 1884.)

Heymann, C. L., Captain and Assistant Surgeon, ordered to proceed to Fort Ontario, N. Y., and report for duty. (Par. 3, S. O., 163, Hdqrs. D. of East, August 3, 1884.)

Kane, John J., Captain and Assistant Surgeon, granted leave of absence for one month. (Par. 1, S. O., Hdqrs. D. of East, August 10, 1884.)

LIST OF OFFICIAL CHANGES IN THE MEDICAL CORPS OF THE NAVY, FOR THE WEEK ENDING AUGUST 16, 1884.

Medical Inspector E. Bogert, to be Fleet Surgeon, Asiatic Squadron.

Surgeon H. I. Babin, detached from Minnesota, ordered to Marine Rendezvous, N. Y.

P. A. Surgeon R. Whitney, detached from Marine Rendezvous, N. Y., ordered to Naval Academy as member of Examining Board.

Surgeon G. H. Cooke, ordered to Naval Academy as member of Examining Board.

P. A. Surgeon P. M. Rixey, detached from special duty at Washington, ordered to U. S. S. "Lancaster."

Surgeon T. Woolverton, ordered to U. S. S. "Minnesota."

ORIGINAL ARTICLES.

DERMATITIS HERPETIFORMIS.

BY LOUIS A. DUHRING, M.D., OF PHILADELPHIA, PA.

Read in the Section on Practice of Medicine and Materia Medica,
of American Medical Association, May, 1884.

Under the name Dermatitis Herpetiformis I propose to place a number of cases of skin disease that I have encountered from time to time. These cases at present are for the most part nameless, having been regarded and diagnosed, either as peculiar manifestations of one or another of the commoner and well-known diseases, as eczema, herpes, or pemphigus, or, in some cases, as undescribed diseases. From these remarks it will be inferred that the disease is rare, and such in a measure is the fact. At the same time I have met with a sufficient number of cases during the last fifteen years, to warrant the view that the disease is worthy of a special description and a name. I first recognized the affection as being peculiar as far back as 1871, but with the few cases observed at that time was at a loss to classify or to treat them satisfactorily. Since this date I have encountered a number of other cases illustrating the same and other varieties of the disease. In the first edition (1877) of my Treatise on Skin Diseases, I made no allusion to the subject, for the reason that my mind was not clear as to the relation that the several cases I had encountered bore one to another, nor that they were really all merely different manifestations of the same pathological process. In the light, however, of a number of marked cases that have now been under observation for a period of years, and of others that have been more recently noted, the statement may be made that, dissimilar as they may in some cases at first sight appear, they all represent varieties of one and the same disease, for which I propose the name "dermatitis herpetiformis."

In the present communication attention will be directed to the principal features of the disease, describing more particularly its symptoms and natural course. On another occasion cases illustrating the several varieties will be brought forward.

It may be premised here that dermatitis herpetiformis includes what Hebra¹ designated first herpes

impetiginiformis and afterwards "impetigo herpetiformis;" that is to say, that the cases of Hebra constitute one of the varieties of the disease it is proposed to call dermatitis herpetiformis. And here it may be remarked that this name must not be confounded with the "dermatitis circumscripta herpetiformis" of Neumann, a term introduced by this author a few years ago to designate lichen planus, which at that time he supposed to be an undescribed disease. It may be added that this term is now no longer used by Neumann.

In the second edition of my Treatise on Skin Diseases (1881) p. 276, under the title "impetigo herpetiformis," will be found an abstract of Hebra's description of the disease he so named.

His account may be summarized as follows: It is a rare and grave form of skin disease, of which, at the date of his report, he had seen but five examples, four of which terminated fatally. The disease is characterized by the formation of yellowish pustules, arranged in groups or in an annular form, which tend to run together and to dry into yellowish, greenish, or brownish crusts, beneath which a red, excoriated, moist surface exists. On the periphery of the lesions and patches new groups and rings of pustules form. The course of the disease was similar in every case. Each outbreak of pustules was preceded by malaise, chills, fever, and systemic disturbance. The disease occupied all regions, with preference for the anterior surface of the trunk and the flexor surfaces of the thighs.

Single cases, under different names,¹ were before this date reported by Bærensprung,² Neumann,³ Auspitz,⁴ and Geber.⁵ Heitzmann⁶ has more recently also reported a case with the name impetigo herpetiformis. As supplementary to Hebra's description, I gave my own experience with hitherto undescribed varieties of the disease in the following language: "*Within the last ten years I have from time to time met with cases, occurring in both sexes, representing other phases of the disease than heretofore described. In some cases the lesions were vesicular and bullous;⁷ in others pustular; in still others, and in the majority*"

¹Wiener Med. Wochensch., No. 48, 1872; The Lancet, March 23, 1872; Atlas der Hautkrankheiten, Heft ix, Tafeln 9 und 10. Wien, 1876.

⁵Jahresb. des K. K. Allg. Krankenhauses zu Wien, Jahrg. 1871.

⁶Archives of Dermatology, January, 1878.

⁷In Hebra's fifth case the disease was characterized by vesicles and blebs, from which circumstance he was inclined to regard the disease as a variety of herpes, and designated it "herpes impetiginiformis." Lancet, March 23, 1872.

¹Wiener Med. Wochensch. No. 48, 1872; see also Lancet, March 23, 1872.

of cases, bullous and pustular combined, or these lesions appearing alternately,—the disease being at one time vesicular and bullous, at another time pustular. In all instances the disposition to group or to extend about the periphery was more or less marked. A varied amount of constitutional disturbance, with violent itching, was always present. The disease manifested a disposition to constant recurrence, in the form of repeated attacks, extending in the majority of cases over years, and was but little influenced by treatment. None of the cases occurred in pregnant women; nor in any case has the disease proved fatal. The disease is liable to be confounded with eczema, ecthyma, and pemphigus, according as the lesions happen to be vesicles, pustules, or blebs. The etiology and pathology of the disease are both obscure. In some cases it possesses many features in common with pemphigus; . . . other cases, however, manifest but little disposition to the formation of blebs. It is therefore evident that the process is capable of appearing in the form of various lesions, and that the true impetigo herpetiformis represents but one variety of the disease. More information is needed before the disease can be assigned its proper place in classification."

These words, written four years ago, give a brief account of the disease which is the subject of this communication, and portray its important features. The description is succinct, but it embraces the leading points, and, it may be added, agrees with the views I hold at the present time.

It will be seen from this description that the name impetigo herpetiformis is altogether inappropriate to express the condition in other and equally important varieties of the disease. The cases that fell under Hebra's observation were for the most part instances of the pustular variety, and he therefore regarded the name he selected as proper; but to call a vesicular or bullous disease "impetigo," with our present ideas of nomenclature, is of course most confusing. Because of the multiformity of the lesions manifested in the several varieties, which will be shown may exist, therefore I think the term dermatitis more suitable, allowing as it does all varieties of this most protean affection to come under its title. The adjective herpetiformis expresses the chief characteristic of the disease, and as in Hebra's cases of the pustular variety, has been present in all of my cases. The disease is unquestionably herpetic, especially in its typical and commonest manifestation, that is, the lesions tend to be vesicular and to occur in small groups or clusters. And for this reason it has on several occasions occurred to me that the affection ought to be regarded as a herpes, an observation that was also made by Hebra, and by the other reporters of cases mentioned. All of these observers recognized its herpetic character.

The name herpes pruriginosus, it might be suggested, or herpes chronicus (as proposed by Neumann) would seem suitable and would answer well for most of the cases observed, itching being always a marked and constant symptom. At the same time, if this term were adopted, our present definition of herpes would require to be changed, and we should be obliged to regard pustular and bullous lesions as man-

ifestations of herpes, an admission which would be confusing, or even disastrous in its results.

For these reasons I think the name now introduced preferable. That such a protean disease as I have intimated exists, and that these varied cutaneous manifestations are all but forms of one pathological process, there can be no doubt, and I shall elucidate this point by describing the several important varieties, which, as in the case of eczema, are based upon the predominance of certain lesions. Before doing this, however, I may refer to certain symptoms common to all forms of the disease, to which no particular allusion has as yet been made. In severe cases prodromata are usually present for several days preceding the cutaneous outbreak, consisting of malaise, constipation, febrile disturbance, chilliness, heat, or alternate hot and cold sensations. Itching is also generally present for several days before any sign of efflorescence. Even in mild cases slight systemic disorders may precede or exist with the outbreak. This latter may be gradual or sudden in its advent and development. Not infrequently it is sudden, one or another manifestation breaking out over the greater part of the general surface diffusely or in patches in the course of a few days, accompanied by severe itching or burning.

A single variety, as for example, the erythematous or the vesicular, may appear, or several forms of lesion may exist simultaneously, constituting what may very properly be designated the multiform variety. The tendency is, in almost every instance that I have observed, to multiformity. There is, moreover, in almost every case a distinct disposition for one variety, sooner or later, to pass into some other variety; thus, for the vesicular or pustular to become bullous, or *vice versa*. This change of type may take place during the course of one attack or on the occasion of a relapse; or, as is often the case, it may not show itself until months or years afterward. I have notes of several cases where, during a period of from two to five years, the erythematous, vesicular, and bullous varieties were all in turn manifested. Permit me, however, again to state that not only multiformity of lesion, but irregularity in the order of development, is the rule, whether during an attack or later in the course of the disease.

Itching, burning or pricking sensations are always present. When the eruption is profuse they are intense, and cause the greatest suffering. As in the case of eczema, before and with each outbreak they become most violent, abating in a measure only with the laceration or rupture of the lesions.

The disease is rare, but is of more frequent occurrence than I formerly supposed. I have encountered fifteen cases, during a period of as many years, drawn from hospital, dispensary and private practice. All, with one exception, were adults, including both sexes in about equal proportion. The natural history is interesting. The process is in almost all instances chronic, and is characterized by more or less distinctly marked exacerbations or relapses, occurring at intervals of weeks or months. The disposition to appear in successive crops, sometimes slight, at other times severe, is peculiar. Relapses are the rule, the

disease in most cases extending over years, pursuing an obstinate, emphatically chronic course. All regions are liable to invasion, including both flexor and extensor surfaces, the face and scalp, elbows and knees, and palms and soles. Excoriations and pigmentation, diffuse and in localized areas, are in old cases always at hand in a marked degree. The pigmentation is usually of a mottled, dirty-yellowish or brownish hue, and is persistent. I have seen it as pronounced as in chronic pediculosis corporis.

The more important forms of the disease may now be considered.

DERMATITIS HERPETIFORMIS (ERYTHEMATOSA).

The erythematous variety manifests itself in patches or as a diffuse efflorescence, as an erythema or superficial inflammation, usually of an urticarial or erythema-multiform-like type. The urticarial element may be marked, the skin showing a disposition to acute œdematous infiltration in a diffuse form. Urticarial complication, rather than urticaria, is suggested by the condition of the skin; in like manner, a resemblance to diffuse erythema multiforme may be noted. At times the patches, whether discrete or confluent, are circumscribed, and later, by their coalition, show irregularly-shaped, marginate outlines, as in erythema multiforme. The color varies with the shape, being at first bright-red, but soon becoming deep-red or violaceous, mottled, and tinged with yellowish hues. The variegation is usually pronounced in the later stages of the process, at which period more or less diffuse pigmentation is also present. Together with the erythematous inflammation there may form maculopapules, or circumscribed or diffuse flat infiltrations, variable as to size and shape; also vesico-papules, the process now bearing a resemblance to the first stage of herpes iris. It will thus be noted that the eruption, in its general aspect and course, is much like that of erythema multiforme. In severe cases the outbreak is preceded by and accompanied with malaise, chilliness or slight febrile disturbance. The itching is generally violent, the disease differing in this respect from erythema multiforme.

Its course is variable. It may continue for days or weeks, or, as is usually the case, it may pass into the multiform variety, to be described later. It may be the first manifestation, or it may follow other varieties as a relapse.

As a variety, it is not as clearly defined as the vesicular, bullous or pustular, in some cases it appearing to be but the first manifestation of one of the first-mentioned forms. But it is important that its features be described, for the reason that it is liable to be met with as a clinical picture, and may readily be confounded with other diseases, notably, urticaria, erythema multiforme or eczema. I recall two cases where the diagnosis was at first difficult, and it was not until other manifestations appeared on the skin that the true nature of the process became evident.

DERMATITIS HERPETIFORMIS (VESICULOSA).

The vesicular variety is that most frequently met with. It is characterized by variously sized, varying from a pin-head to a pea, flat or raised, irregularly shaped or stellate, glistening, pale-yellowish or pearly,

usually firm or tensely distended vesicles, as a rule, unaccompanied by areolæ. In their early stages they can be seen only with difficulty, and are liable to be overlooked in the examination. Sometimes they can only be detected or seen to advantage in an oblique light. This observation I have repeatedly noted, and arises from the fact of the lesions being flat, translucent and without areolæ. In size they vary extremely, large and small being formed side by side, and in this respect they differ from the vesicles of eczema. Here and there papules, papulo-vesicles, vesico-pustules and small blebs will sometime be encountered. Concerning their distribution, the eruption as a whole is disseminate, the lesions existing scattered more or less profusely over a given region, as, for example, the neck or the back, but they are for the most part aggregated in the form of small clusters or groups of two, three or more; or there may be patches here and there as large as a silver dollar, upon which a number will be seated. When in close proximity they incline to coalesce, as in herpes zoster, forming multilocular vesicles or small blebs. Where this occurs they are generally slightly raised and are surrounded with a pale or distinctly reddish areola, which shows forth the irregular, angular or stellate outline of the lesion. At this stage, moreover, the little cluster will generally present a "puckered" or "drawn up" appearance, indicative of its herpetic nature.

The eruption is usually profuse, sometimes to the extent of the upper extremities, trunk and thighs being well covered. It may attack any region, the neck, chest, back, abdomen, upper extremities, and thighs all being especially liable to invasion.

The most striking symptom is the itching. Not infrequently burning is also complained of. Itching, however, predominates, and is in all cases violent or even intense. Patients state that it is altogether disproportionately in excess of the amount of eruption. It is, moreover, a persistent itching, causing the sufferer to scratch constantly. It generally precedes the outbreak, and does not abate until the lesions have been ruptured. Old sufferers, familiar with the natural course of the process, have informed me that they can obtain no relief until the lesions have been ruptured. From my observation I should say that the itching was both more severe and more lasting than in vesicular eczema. The vesicles make their appearance slowly, so that several days, or a week, may be required for their complete development. Notwithstanding that scratching is indulged in in the early stages of the disease, excoriations are not prominent, owing to the fact that the walls of the lesions are tough, and do not rupture, and that they incline to re-fill immediately on being evacuated.

The diagnosis in some cases is attended with difficulty, on account of the resemblance to vesicular eczema. I recall the embarrassment experienced in the classification of the earlier cases encountered, and the provisional diagnoses of "vesicular eczema?" made at the time. But the irregularity in the size and form of the vesicles; their angular or stellate outline; their firm, tense walls, with no disposition to rupture, and their herpetic character, will all serve

to aid in the diagnosis. In some cases the constitutional disturbance and the magnitude of the eruption, as regards profusion, distribution, and uniformity, showing a more formidable disease than eczema, will also be striking. The itching and burning will usually be found to be more continuous and intenser than in eczema. The obstinacy of the disease to the ordinary treatment of eczema, moreover, must also soon become apparent, the usual milder remedies so frequently of service in acute vesicular eczema, being of little or no benefit in this disease. Finally, the tendency to repeated relapses, and the chronicity of the affection, must strike the observer as peculiar. This variety cannot be confounded with herpes zoster, herpes iris, or pemphigus. Its relations to the "herpes gestationis" of some authors will not be considered in this paper, further than to state that in my opinion they are probably one and the same disease. On a future occasion I shall deal more at length with this point.

DERMATITIS HERPETIFORMIS (BULLOSA.)

In the bullous variety the lesions are more or less typical blebs, tense or flaccid, rounded or flat, usually the former, filled with a serous or cloudy fluid, seated upon a non-inflammatory or slightly inflamed base. In size they vary from a pea to a cherry or walnut, and are for the most part irregular or angular in outline. They incline to group in clusters of two or three, the skin between them in this event being reddish and puckered. Sometimes in immediate proximity—almost contiguous—will exist one, two or three, or a part of a circle of small, pin-head sized, flat, whitish pustules. Vesicles of all sizes, flat or raised, are also generally found near by or disseminated over the affected surface. As in the other varieties, all regions may be attacked, especially the trunk, upper extremities and thighs. In several cases I have seen the greater part of the general surface invaded most profusely, in which event the lesions are usually smaller than where comparatively few exist. They incline to appear in crops at irregular intervals, as in the other varieties. The lesions are generally ruptured in the course of a few days and then crust over with a yellowish, greenish or brownish crust. They are accompanied by burning and itching, which may be very severe. They bear resemblance to those of pemphigus vulgaris, with which of course they may be readily confounded, but they are more herpetic in character. They differ in that they incline to group, and have a more inflammatory herpetic aspect, the type of which picture is seen in herpes zoster. Moreover, around and near the bleb will usually be found vesicles and pustules, the latter often in close proximity, the whole manifestation being quite different from that of pemphigus.

DERMATITIS HERPETIFORMIS (PUSTULOSA.)

The pustular variety is generally less clearly defined than the vesicular, because the lesions are often intermingled with vesicles, vesico-pustules and blebs. In typical cases the pustules are acuminate, rounded or flat, tense or flaccid, usually the former, and vary in size from a pin-point to a pea or silver quarter-dollar. Vesicles and blebs in some cases precede the

pustules. The smallest lesions are generally flat, or on a level with the surrounding skin, and, as stated, are frequently not larger than a pin-point or pin-head. Larger pustules, the size of a pea, are generally rounded or acuminate, and are surrounded by a reddish inflammatory areola. Later they incline to flatten, and to increase in size by spreading peripherally, and drying in the centre.

Sometimes they are seated on a slightly raised base. When fully matured they generally present an "angry" appearance, the skin immediately around them having a "puckered" look, from the fact that the pustule itself is irregular in outline, as sometimes is the case in herpes zoster.

They incline to form in groups of two, three or more, and moreover, often appear in patches of two or more groups. Such an arrangement is generally met with on the trunk. The grouping is further peculiar, in that a central pustule will often be immediately surrounded by a variable number of smaller pustules, sometimes in a circinate form, as in herpes iris.

In other localities, however, no such peculiarity occurs, the lesions being discrete, and even disseminate. The pustules are usually opaque, and of a whitish color; sometimes they are yellowish, though they are seldom so yellowish as in pustular eczema. Not infrequently slight hæmorrhagic exudation occurs, as in the later stages of herpes zoster, giving them a reddish, bluish or brownish hue. They are generally accompanied by sensations of heat, pricking or itching; in some cases these symptoms precede for several days the eruption. They pursue a slow course, from one to two weeks being usually necessary for their full development; in other cases their maturation occurs more rapidly. In some cases, together with the pustules are found vesicles and blebs of various shapes and sizes, and these often form immediately by the side of, or in close proximity to, the pustules. Papules and papulo-vesicles may also be present. In a given area, say of a few square inches, as for example upon the abdomen, there may exist all of these lesions in various stages of evolution. This multiformity is striking, and presents a curious and peculiar mixture of lesions. The attacks last from two to four weeks, after which there generally follows a comparative respite of from one to six weeks. The disease may thus be kept up indefinitely, the outbreaks being at one time slight, at another time severe.

Sometimes it has preceded other varieties; in other cases it has followed the bullous variety; while in some instances that have been under observation for a long period, it has at intervals of months alternated between the vesicular and bullous varieties. After what has been previously said, it need scarcely be stated that this variety is identical with the "impetigo herpetiformis" of Hebra, although in but few of the cases observed by me have the symptoms been so pronounced as in Hebra's experience, if I may judge from the portraits in his Atlas of Skin Diseases. The account given by me relates to the disease as I have encountered it. Hebra's account has been already given, and need not be repeated here. The differ-

ence of experience concerns chiefly the severity of the process. Thus, in none of my cases has it proved fatal, while it will be remembered four out of five of Hebra's cases died, and according to Kaposi¹ (Hebra's successor), ten out of eleven cases observed by him have perished. Finally, I have observed it to occur about as often in men as in women, and also in the latter apart from pregnancy. Hebra, on the other hand, met with it only in women, and, moreover, only during the parturient state.

Concerning the constitutional symptoms, they may be stated to vary with the gravity of the attack. Usually, however, they are more marked than in the other varieties, rigors and alternate paroxysms of heat and cold being especially noticeable. It is the most serious phase of the disease.

DERMATITIS HERPETIFORMIS (PAPULOSA).

The papular variety is in my experience rarer than any other form. I have met with only two cases, one in an adult, the other in a boy, and in both of these the eruption was scanty. It is characterized by the formation of small or large pea-sized, irregularly-shaped, usually firm, reddish or violaceous papular lesions, occurring for the most part in groups of two or three, scattered here and there over the affected surface. They are of variable size, large and small ones not infrequently existing side by side, and are as a rule ill-defined, being neither acuminate nor flat, but resemble the papular infiltrations sometimes met with in abortive herpes zoster. They are of an acute or subacute inflammatory type, and, as stated, bear resemblance to abortive herpetic lesions, and also to certain phases of chronic relapsing papular eczema. Their surfaces are generally excoriated, from scratching, and may be covered with blood-crusts, or with slight, adherent, thin epidermic scales.

The itching is severe, so much so that comparatively few lesions may so torment the patient as to interfere with the night's rest.

Ill-defined papulo-vesicles are also met with here and there, as in the case sometimes of papular eczema. The lesions pursue a slow, chronic course, lasting from one to two or four weeks, when they gradually disappear, leaving more or less pigmentation. Relapses are the rule at longer or shorter intervals.

As I have intimated, this variety bears a close resemblance to chronic papular eczema, and the earlier cases encountered by me were so diagnosed, but the irregularity in the size and form of the lesions; the disposition to group; the usually slow evolution of the lesions; the tendency to appear in crops at irregular intervals; the chronicity of the process; and the extreme obstinacy to local and internal treatment, are all peculiar. It is the mildest phase of the disease.

DERMATITIS HERPETIFORMIS (MULTIFORMIS).

This may be regarded in the light of clinical variety, one that is eminently useful from a practical standpoint. It is a variety of the disease in the same sense that eczema rubrum is a variety of eczema. It

is important to consider it for the reason that it is a picture which may at any time show itself in the course of the disease. It is a phase not infrequently met with, and on account of the great mixture of lesions and the difficulties presented in diagnosis, is worthy of special description. The multi-form variety consists of erythematous, sometimes slightly raised, urticarial patches of variable size and outline, often confluent, of a reddish or violaceous, yellowish, dusky, sometimes variegated, color, not unlike that of erythema multiforme. In addition, there often exist more or less well-defined, irregularly shaped or rounded, maculo-papules and flat infiltrations, papules and vesico-papules, all in various stages of evolution. Small blebs and pustules, pin-point sized or larger, may also be present, though with the vesicular element predominating it is not usual to meet blebs or pustules of large size nor in numbers. As the disease is in an early or late stage of its existence, will pigmentation and excoriations be slight or marked. Briefly, then, to recapitulate, there exists a mixture of lesions, with no single type predominating, calling to mind in its behavior eczema, although it is far more capricious and protean. It must also be remembered that the process may at any period change its type, such an occurrence usually taking place with an exacerbation or a relapse. Thus, the vesicular variety may exist for a variable period, to be followed in a few weeks or months by an attack of blebs, or it may be pustules, or by a mixture of the blebs and pustules. This mingling of several varieties is a marked and peculiar feature of the disease, giving a very striking dermatological picture, different from that seen in any other disease of the skin.

In conclusion, permit me to summarize by saying that I have endeavored to show:

1. The existence of a distinct, well-defined, rare, serious, inflammatory disease of the skin, manifestly of an herpetic nature, characterized by systemic disturbance, a great variety of primary lesions, by severe itching and burning, and by a disposition to appear in repeated successive outbreaks.

2. That the disease is capable of exhibiting itself in many forms, all having a tendency to run into or to succeed one another irregularly in the natural course of the process.

3. The principal varieties are the erythematous, papular, vesicular, bullous and pustular, which may occur singly or in various combinations.

4. That it is a remarkably protean disease.

5. That the pustular variety is the same manifestation as the disease described by Hebra under the name "impetigo herpetiformis," this being the only form hitherto described.

6. That the several other and equally important forms are worthy of special remark.

7. That the term "dermatitis herpetiformis" is sufficiently comprehensive and appropriate to include all varieties of the process.

8. That it may occur in both sexes, and in women independent of pregnancy.

9. That it usually pursues a chronic, variable course, often lasting years, and is exceedingly rebellious to treatment.

¹Pathologie und Therapie der Hautkrankheiten, 2te Auflage, Wien, 1883.

A PERIODICAL PAINFUL AFFECTION, BELIEVED TO BE LOCATED IN THE LIVER, ITS CAPSULE, OR BOTH, OR POSSIBLY AN IRRITATION OF THE CAPSULE OF GLISSON.

BY R. HARVEY REED, M.D., MANSFIELD, OHIO.

Read in the Section on Practice of Medicine and Materia Medica of American Medical Association, May, 1884.

Although the anatomy of the Capsule of Glisson was carefully pointed out by Dr. Francis Glisson in his work on "The Anatomy of the Liver" as early as the middle of the sixteenth century; and although occasionally ever since, medical writers have hinted at diseases of this tunic, yet after a review of many of their writings, and after comparing them with the condition we have designated as above, we are forced to conclude that it is a separate and distinct disease, readily recognizable from associate diseases of the liver, and meriting a distinct place of its own in the catalogue of hepatic maladies.

DEFINITION.

For the sake of brevity we will only use the term "Irritation of the Capsule of Glisson," to designate this disease which we believe to be a rheumatoid irritation of a part or all of the connective tissue which forms the inner tunic of the liver and envelops the portal vein, hepatic artery and duct, together with the lobules of the liver.

It is characterized by intermitted pain, of a burning, boring, throbbing, darting or lancinating character, occurring usually at night, but unattended with signs of inflammation, by chill, fever, constipation, loss of appetite or headache.

FREQUENCY.

Whilst quite rare in comparison with the more common hepatic diseases, yet this condition occurs sufficiently often in this region to merit special attention by every practicing physician.

My friend, Dr. J. W. Craig, of Mansfield, Ohio, who has had thirty years of active practice in the profession, and to whom I am indebted for having first called my attention to this condition, reports having treated over one hundred cases in the last twenty years, or an average of five cases a year.

I have seen and treated directly or indirectly twenty-five cases in the last six years, or an average of over four cases a year.

CAUSES.

The causes which seem most clearly to lead to this disease are sedentary habits.

In fact neither Dr. Craig nor myself have ever met with it in strictly active persons, but invariably in those who had led an inactive life, or were more or less confined in their occupations.

Hence it has been observed to occur more frequently in women than in men, and in persons of middle or advanced age than in children or young persons; in fact I never knew of it occurring in the latter.

We have met it oftener in persons engaged in the following occupations or professions than in all others put together; which we have arranged in the relation of their frequency, commencing with the most frequent:

Dressmakers, engineers, ministers, book-keepers, saddlers, printers, shoemakers, tailors, sewing-machine agents, merchants, and one case in that of a boiler-maker, and one occurring in a farmer's daughter.

It is seldom found in persons addicted to intemperate habits, but rather in persons of unquestionable temperate habits and with no history of syphilis either constitutional or acquired.

This disease has been noticed to occur most frequently during those times of the year when rheumatism is most prevalent, although it may occur at any time.

SYMPTOMS.

The premonitory symptoms of this disease come on so insidiously, that the patient is scarcely aware that he is afflicted with more than a "slight colic," or a "touch of neuralgia," or "the cramps," as they will often express it, until it gradually increases in frequency and severity, and perhaps his attention is called to the fact of its periodical returns every few nights, which very greatly disturbs his nocturnal rest.

He generally goes to bed feeling perfectly well, but after a few hours' sleep is awakened with burning, shooting pains in the region of the liver, which keep him awake or compel him to walk his room for an hour or so, or perhaps till morning, before it subsides.

Generally by morning, in the less advanced stages of the disease, the pain subsides and the patient feels as well as usual, and goes to his work thinking "that is all there will be of it," until in a few days he has a repetition of the same, excepting it has increased somewhat in severity, or is more prolonged than the previous attack.

Thus it creeps on gradually, until the attacks of pain become so severe as to warrant his calling a physician, who may find his patient walking the room in agony, or rolling from side to side of the bed, or sitting tailor fashion with the arms folded across the bowels and rocking to and fro. This motion he will sometimes keep up for hours, asserting that "nothing else gives him as much relief," or that "he would die" if he were to stop it.

Upon interrogation, it will be found that these attacks, which at first were weeks apart, are now separated by an interval of a few days only; or perhaps they occur every night, generally coming on about the same time each night, and with but few exceptions after the patient had fallen asleep.

After the attack subsides the patient feels somewhat exhausted, with perhaps a slight tenderness over the hepatic region, but otherwise appears to be in usually good health—so much so that he imagines every attack is certainly the last, until experience induces him to be skeptical of the most favorable symptoms.

If relief is not afforded, these attacks, which at first only last a few minutes, will gradually increase in duration to several hours, or even days, with but very slight interruption.

The pain in these attacks is described as burning,

boring, cutting, shooting, aching, throbbing or lancinating, generally, however, of the character of the first two, sometimes described as a "coal of fire in their right side."

It is confined almost entirely to the hepatic region, at times almost entirely to the front and right side, and at others extending around to the back, but seldom any pain is complained of on the left side.

A physical examination reveals a normal or but slightly accelerated pulse, and a normal temperature, a moist, although at times a slightly furred tongue, little or no headache. Occasionally there is a slight sallowness of the skin in the advanced stages of this disease, but there is seldom jaundice.

The appetite is usually good, although at times it is irregular, and occasionally it is poor. Now and then there is vomiting, which generally comes on during a severe attack of pain, when present at all, I having seen it in only one case, and Dr. Craig in but a few.

An examination of the liver reveals but slight enlargement at any time, and often none at all; and but little tenderness even during the attack, and little or no tenderness in the intervals except in cases of long standing.

There is no perceptible hardening of the gland or tendency to a nodulated or so-called "hobnailed" condition.

The bowels are seldom constipated, except in cases which, as patients say, are "naturally so."

The stools are normal in color, regularity and consistency, and after repeated examinations have never been found to contain gallstones.

The urine is generally normal in color, quantity and chemical composition.

The skin is moist, and there is but slight emaciation or general debility, except in very advanced and long continued cases.

DIAGNOSIS.

The diagnosis of this so-called irritation of the capsule of Glisson, whilst somewhat difficult at first, will soon be found to have such distinctive features centered around it, as to render this malady easily distinguished from associate abnormal diseases of the hepatic gland.

The diseases for which it might be mistaken are the "passing of gallstones," "interstitial hepatitis," "congestion of the liver," "perihepatitis," "inflammation of the bile-ducts," "cirrhosis" and "hepat-algia."

If the following differences are borne in mind, there will be little or no danger of mistaking this disease for the passing of gallstones:

PASSING OF GALL-STONES.

The attacks commence suddenly, and may reach their maximum of severity in the first attack.

The attacks may come on at any time, often just after a meal, a drive over rough roads or violent exercise

IRRITATION OF THE CAPSULE OF GLISSON.

The attacks do *not* commence suddenly, but come on gradually, increasing in severity with each returning attack.

The attacks nearly always come on at night, seldom immediately after a meal or violent exercise.

There is frequent vomiting.

Colicky, tearing pains.

Marked temporary jaundice may occur from obstruction.

A careful examination of the feces will often reveal gallstones after an attack.

Seldom any vomiting.

Burning, boring, throbbing pain.

Seldom ever is there any jaundice.

Gallstones are never found in the stools after an attack.

A careful observation of these few differential symptoms will seldom fail to enable the practitioner to make a clear diagnosis between these two conditions. It is possible to confound this disease with interstitial hepatitis, although it is generally very easily distinguished by the following differences:

INTERSTITIAL HEPATITIS.

Generally associated with alcoholic intemperance.

Venous stigmata on the cheeks

Pain and irritation over the liver more or less constant

More or less jaundice.

Nausea and vomiting, especially on first rising in the morning.

Loathing of solid food, particularly in the morning.

Diarrhoea and constipation alternating with each other.

Urine very scanty and dark colored.

Occasional pyrexia.

Often portal obstruction.

Enlargement followed with contraction of the liver.

Often has a distinct syphilitic origin.

Sometimes comes on with a chill.

May have ascitis.

Emaciation and general debility.

A dry, harsh skin.

IRRITATION OF THE CAPSULE OF GLISSON.

Seldom associated with alcoholic intemperance.

No venous stigmata on the cheeks.

Pain coming and going in paroxysms.

Sometimes slightly sallow, but seldom jaundiced.

Seldom any nausea or vomiting.

Appetite generally good, or but slightly impaired.

Bowels seldom out of order.

Urine generally normal or nearly so.

Seldom, if ever, any pyrexia.

No portal obstruction.

Seldom any or but slight enlargement, and never followed by contraction of the liver.

Seldom has a clear syphilitic origin.

Never has been known to be preceded by a chill.

Never has ascitis.

Emaciation not marked, and but slight or at times no debility.

Skin not dry and hard.

By a comparison of the following diagnostic points, we can readily distinguish this disease from hepatic congestion.

CONGESTION OF THE LIVER.

Enlargement of the liver.

A continued feeling of tightness, or painful distention over the liver.

Jaundice is nearly always present.

Nausea and loss of appetite.

IRRITATION OF THE CAPSULE OF GLISSON.

Little or no enlargement of the liver.

No feeling of tightness or distention, but a deep burning, boring, lancinating pain of a paroxysmal character.

Jaundice is seldom present.

Seldom nausea or loss of appetite.

Indigestion, furred tongue and headache.	Seldom troubled with indigestion, but slightly furred tongue and seldom any headache.
Vomiting and often diarrhoea, or both.	Seldom any vomiting or diarrhoea.
More or less dyspnoea.	Seldom ever the slightest dyspnoea.
More or less stupidity and drowsiness.	Seldom any stupidity or drowsiness.
Often signs of obstruction to portal circulation.	No signs of obstruction to portal circulation.
Urine scanty and high colored, with more or less bile.	Urine normal or nearly so.
Temporary albumenuria often occurs.	Albumenuria has never been known to occur.
The attacks continue without interruption until the congestion subsides.	The attacks come on by paroxysms, between which the patient feels quite well.

Irritation of the capsule of Glisson may also be confounded with perihepatitis, which is more particularly an inflammation of the peritoneal covering of the liver, which inflammation may also extend to Glisson's capsule, which is generally the result, or it may be the consequent of acute peritonitis, or some organic disease of the liver.

It may also be the result of traumatic causes, or the spreading of inflammation from adjacent tissues, and is always ushered in with a chill and followed with fever, pain, and superficial tenderness, together with all the symptoms of inflammation.

On the other hand, in irritation of the capsule of Glisson, there is no peritonitis, and it is not ushered in with a chill or followed by fever or inflammation, and is not continued without interruption, but is paroxysmal and free from fever and inflammation.

The chief diagnostic points between this disease and "inflammation of the bile ducts" may be briefly summed up as follows:

INFLAMMATION OF THE BILE DUCTS.	IRRITATION OF THE CAPSULE OF GLISSON.
Generally met with in children or old, gouty persons.	Never met with in children, and not more frequently in old, gouty persons than ordinarily healthy persons of middle age.
Partial or complete obstruction of the bile ducts.	No obstruction of the bile ducts.
Jaundice.	No jaundice.
Preceded by gastro-duodenal catarrh.	Not preceded with gastro-duodenal catarrh.
Usual signs of inflammation. The inflammation usually commences in the mucous membrane of the digestive canal and extends from there to the bile ducts.	No symptoms of inflammation. No inflammation of the digestive tract, and is not communicated from the alimentary canal.
Pulse is abnormally slow.	Pulse not particularly changed.
Frequently the stools contain no bile.	The stools are usually normal.

The differential diagnosis of "irritation of the capsule of Glisson" and "cirrhosis of the liver" will require some attention. Whilst it is generally easy, there are points of similarity which might be the means of leading the unguarded astray.

CIRRHOSIS OF THE LIVER.

Is often the result of chronic interstitial inflammation.

Intemperate habits very frequently cause cirrhosis.

Is found in males oftener than in females

Is nearly always fatal.

Is frequently the result of syphilis.

All the general symptoms of acute congestion of the liver, together with those of gastro-enteric catarrh.

Marked constitutional disturbance.

Frequently there is ascites.

Hæmorrhage from the stomach or intestines

Enlargement of the spleen.

Digestive disturbance very prominent.

As the disease advances the acute pain subsides.

Jaundice in the commencement of the disease, but often more in the advanced stages.

Diminution of hepatic dullness in proportion to the contraction.

Nodulated feeling of the surface of the liver

Dry, harsh skin, with flabby tissues.

Often extensive ecchymosis and hæmorrhage from the mucous surfaces.

IRRITATION OF THE CAPSULE OF GLISSON.

Is not the result of chronic interstitial inflammation.

Is not caused by intemperate habits.

Is found in females oftener than in males.

Has not been known to be directly fatal.

Is not necessarily the result of syphilis.

Seldom any marked symptoms of hepatic congestion or gastro-enteric catarrh.

Little or no grave constitutional disturbance

Never has been complicated with ascites.

Never have hæmorrhage from the stomach or intestines.

No enlargement of the spleen.

Digestive functions seldom disturbed.

As the disease advances the acute pain increases.

Jaundice seldom is present, and if present at all is more apt to occur in the advanced stages.

No diminution of the hepatic dullness.

No nodulation of the hepatic surface.

Skin not dry and harsh, and the tissues not flabby.

No ecchymosis, and never any hæmorrhage from the mucous surfaces.

Irritation of the capsule of Glisson might possibly be mistaken for hepatalgia.

The supply of nerves, however, to this organ, being scanty in comparison to its size, most of which are supplied from the solar plexuses, with a few branches from the pneumogastric, which follow the ramifications of the hepatic artery, would impress us at once, that it is an organ not particularly predisposed to neuralgic affections, and when present at all, will always be found in extremely nervous or hysterical persons, and most generally in females about the time of their menses.

This disease is so rare that Dr. Murchison says: "I do not remember to have met myself with an unmistakable example of hepatic neuralgia."¹

Since hepatalgia is a purely functional disease, and occurs so rarely, when it does occur, a careful observation of the general appearance and history of the patient, together with the causes and symptoms of the two diseases, will readily enable the practitioner to diagnose between these two morbid conditions.

DURATION.

Irritation of the capsule of Glisson, if not arrested, may continue for months or even years, with a gen-

¹ Clinical Lectures on Diseases of the Liver, p. 485.

eral tendency to get worse—the attacks coming on more frequently and increasing in severity, with no tendency whatever to get well itself.

PROGNOSIS.

The prognosis of this disease is exceedingly favorable. Whilst it may linger for months, and in a few cases I have known it to continue for years, neither Dr. Craig or myself have as yet ever seen a fatal case. If, however, it is subjected to proper treatment, it usually subsides in a much shorter time—from a few days to a few weeks, under such treatment, the attacks come on less frequently, continue for a shorter time, and are much less severe each return, until they disappear entirely, and the patient returns to the enjoyment of his usual health.

On the other hand, I have seen these cases resist the most vigorous line of improper treatment for months, and even years, which yielded to suitable remedies in a few days or weeks, and have never had a return of the disease since.

COMPLICATIONS.

The complications which are most likely to occur with this disease are rheumatism, and occasionally malaria, although any of the diseases to which the liver is subject may be associated with it.

PATHOLOGICAL ANATOMY.

No fatal cases having occurred either in my own practice or in that of my friends, I have therefore, as yet, nothing to offer on the morbid anatomy of this affection.

TREATMENT.

I know of no disease which is more satisfactorily influenced by a proper treatment than the one we are now considering, and also know of none which is more tenacious when not properly treated.

The remedies which have given the most satisfactory results in this malady are alkalies combined with a bitter tonic.

The combination most frequently used by Dr. J. W. Craig, and one which I have found very satisfactory (excepting its disagreeable taste) is the following:

R Sodii bi-carb. ʒiv.
Pulv. hydrastis can. ʒi.

M.

S. Use a teaspoonful in two-thirds of a glass of water before eating.

If, however, there is a tendency to constipation, I have found the following to give prompt relief:

R Sodii sulph., C. P. ʒv.
Hydrastia sulph. gr.v.
Aquaë ʒiii.
Glycerinæ, q. s. ad. ʒiv.

M. S.—ʒi before each meal and before retiring.

Sodii et pot. tart. combined with infusion of gentian has given good satisfaction in some cases, or a Seidlitz powder before each meal, followed with a capsule of cinchoninæ sulph. and pepsin after eating, especially if there is any complication of malaria or gastric irritation.

My experience in the large majority of these cases has prejudiced me in favor of the first two formulæ, which indicate the general line of treatment I have

been most successful with, but which must be modified to suit each particular case.

Where there are marked rheumatic complications good results may be obtained by combining the soda with salicylic acid (that made from the oil of wintergreen is preferred) or salicin, to which may be added the iodide of potassium and ext. of colchicum seed.

Mercurials, as a rule, are not well tolerated—in fact, they have always seemed to aggravate the disease every time I have used them in it.

All stimulants as well as condiments are better avoided, and the patient advised to live on a good nutritious diet, and eat regularly and take plenty of exercise.

Frequent baths of chloride of sodium or the hypsulphite of soda, followed with a brisk rubbing, will very materially assist the treatment, while active exercise should be speedily substituted for the sedentary habits generally practiced by this class of patients.

Frequently the physician is called in the midst of one of these severe attacks of pain, and is urged to give speedy relief.

This can be best accomplished by a hypodermic injection of an eighth or a sixteenth of a grain of sulph. of morphia. Hot fomentations, hot water bags or hot bricks applied over the hepatic region, assist very much in affording relief to the sufferer.

The use of anodynes, however, either internally or by hypodermic injection, should be suspended at the earliest possible moment, for they retard the improvement so desirable in every case.

In order to illustrate this disease, I will report a few cases, which may be fairly considered average cases:

Mrs. A., æt. 38. Had been married for ten or twelve years. Was a large, muscular, robust woman, and had always enjoyed good health. Had no children, and no history of ever having had a miscarriage. Had lived most of her life on a farm, but in late years had moved to town and engaged in dress-making, which kept her closely confined early and late, with but little exercise.

Was first taken ill in 1877, and suffered very much for several weeks, so that she was compelled to give up her work, and returned home and went at house-work. In a few weeks she had improved so much that she returned to the dressmaking again.

In 1878 she was taken ill again, and called on her family physician for relief. The persistence of the trouble compelled her once more to give up her sedentary habits, after which her health soon began to improve; but on returning to it was soon attacked more severely than ever, and feeling discouraged changed physicians.

It was evident from her description of the treatment that her former physician had been treating her for malaria. After she had taken treatment for some time with the second physician, it was evident that he too was not meeting with success, and the author was invited to see her, who was also led astray by the periodicity of the attacks which always came on at night.

Having ascertained that both her medical attendants had freely given her of mercurials and quinine

together with morphia to control the pain, and without any success, I was at once impressed that there was something peculiar about the case not yet observed.

When first called I found her sitting on a lounge "tailor fashion" with arms folded across the bowels, rocking to and fro and crying with pain which she located in her right side.

It was described as a burning, boring, lancinating distress, over the region of the liver. She informed me she had been feeling pretty well during the day, and had retired feeling comfortable; but in a few hours was awakened with this severe pain. She informed me she had been having these attacks almost every day of late, and that they were getting very much worse. I also learned from my patient that they did not come on with a chill, that her appetite was good and her bowels regular except when she took morphine to relieve the attacks of pain.

I found her pulse slightly excited, but otherwise normal, the tongue was moist and but slightly furred; no aching in the back or limbs.

I found she had been taking morphine so long that it had but little or no effect on her except in large doses, consequently I put her on an anodyne consisting of cannabis indica and hyoscyamus, and applied hot applications over the seat of pain, and supposing it to be of malarial origin, put her on quinia and arsenic.

On returning the next day I found my patient up and around her work and apparently well. I left her some rhubarb to open the bowels, ordered the anodyne discontinued and the quinia and arsenic vigorously pushed.

I obtained some urine for chemical and microscopic examinations, and suspecting gallstones, ordered the feces kept and carefully washed, with a view of capturing any offending material of that character.

On examination I found the urine quite normal, and repeated washings of the stools failed to reveal any gallstones, which increased my faith in the malarial hypothesis.

The second night following I was again called about midnight, and found her repeating the drama of the night before, only if anything worse, which, in spite of all my treatment continued to grow worse.

The case was examined and reexamined, there was no jaundice, no enlargement of the liver, little or no indigestion, no headache to speak of, no chills, and no fever, or sweating except the perspiration induced by the severe pain, and still these attacks of pain kept on getting worse in spite of all my efforts.

I finally advised counsel and requested the family to call Dr. Craig, of Mansfield (the author was then a resident of West Salem, some thirty miles distant from the above place), who came in a few hours and diagnosed the disease an irritated condition of the capsule of Glisson—a malady which at that time the writer was not at all familiar with.

The doctor advised me to put the patient on sodii bi-carb. combined with pulv. hydras. canadensis, to be given in water previous to each meal; he advised the continuing of the hot applications when the attacks of pain came on, and if absolutely necessary

some suitable anodyne until she could endure the attacks of pain without it. Under this treatment my patient made a rapid and complete recovery and now, over six years after, has never had a return of the disease since to my knowledge.

CASE II. Mr. B., æt. about 35, a saddler by trade, who was under the care of a neighboring physician for months, without any improvement, but rather grew worse. The doctor finally became discouraged and presented him as a clinical case at a meeting of the Northeastern Ohio Medical Association for counsel and advice.

Prof. D. B. Smith, of Cleveland, together with Dr. Starr and myself, were appointed to examine his case.

Dr. Bucher stated that his patient was very greatly harassed with periodical attacks of pain coming on after he had retired, almost every night.

He stated that his patient would work all day at his trade, but after retiring, would be awakened by a severe pain located over the region of the liver, of a burning, shooting character.

These attacks were progressive in severity and frequency until they were occurring almost every night, and were so severe as to deprive him of most of his night's rest.

On inquiry, he revealed no history of syphilis or intemperance, and none of malaria except the periodical nature of his attacks of pain, but lest there should have been some mistake in his history, Dr. B. said he had treated him at different times most vigorously for the first and last maladies, but without relief. He had searched carefully for gallstones in vain, examined the urine and found it normal, had given him liberal doses of mercurials, "in fact" (to use the doctor's words) "I have had him over the materia medica from beginning to end, and nothing I have given him has done him any good."

After a careful examination it was agreed on by the committee that he had "irritation of the capsule of Glisson," and accordingly he was put on the soda and hydrastis treatment, as previously described in this paper.

In a few weeks after I received a card from the doctor stating that his patient was feeling quite well, that he soon commenced to improve after putting him on the prescribed treatment.

More than a year after I met the doctor, who told me that the patient had made a complete recovery, and was now enjoying good health.

CASE III. Dr. B., æt 75, a clergyman, who had always been a close student, called on the writer in March, 1882, and gave the following history:

In December, 1881, he began to suffer some from distress, which he referred to the stomach, although the appetite remained fair; he informed me that he had been troubled more or less with distress up to February, 1882, when he discovered that eating lemons gave him relief, until about the first of March, when the burning pain commenced under the short ribs on the right side, generally coming on at night.

Notwithstanding he was under the treatment of his family physician, he observed this pain was steadily increasing, both in severity and frequency, until it came on almost every night; subsiding during the

day only to awaken him the following night, until it grew so bad that he decided to change his medical adviser and called the writer.

When I first saw him he was suffering intensely with a burning pain in his right side, which, after eliciting the above history, awakened my suspicion of the existence of irritation of the capsule of Glisson. This suspicion was increased when he informed me, he had been able to continue his clerical duties up to the present, although, as he said, he could rest but little on account of the intense agony he was obliged to endure at night.

On examination, I found the pulse normal and the patient free from fever, tongue moist, and but slightly furred, appetite good, stools about normal, and free from gallstones; there was slight constipation at times, urine but slightly changed; some tenderness over the liver, but not much, with very slight enlargement, no jaundice, although his complexion was at times somewhat sallow.

There was no headache or drowsiness, and he was free from backache, or pain in the limbs.

These symptoms, together with his history, confirmed my opinion as to it being a case of irritation of the capsule of Glisson I had to deal with.

I put him on *sodii bi-corb.* and *pulv. hydrastis canadensis*, to which I afterward added a tonic of gentian with an occasional laxative dose of *sodii et pot tart.* which was interchanged with an occasional vegetable laxative.

Hot applications were made over the liver during the attacks of pain, but did not resort to the use of anodynes.

In a few days I found my patient beginning to improve, the attacks of pain becoming less severe, and not so frequent; and in less than a fortnight I was enabled to dismiss him, feeling quite comfortable, the attacks having subsided entirely. He continued the use of the *sodii* and *hydrastis*, however, for a few weeks after he was dismissed.

I saw him a few days before I left home, and he reports never having enjoyed better health in his life, and has had no threatening of the return of the disease since.

Were it necessary, I might multiply these reports, but the above cases which have been selected as typical cases, and which have occurred along with many others, at intervals covering a period of six years, will serve to illustrate the disease I am endeavoring to describe.

In presenting this paper I do not expect to escape criticisms. I am fully conscious of its incompleteness, and regret my present inability to accompany it with more thorough and satisfactory investigations than those furnished.

This paper may, however, serve to call the attention of others to the train of symptoms herein illustrated, and that they may in this manner be ultimately properly explained.

THE COMMUNITY OF ORIGIN OF DIPHTHERIA, TYPHOID FEVER AND SCARLATINA.¹

BY E. O. BARDWELL, M.D., OF MOLINE, ILL.

It will not be expected that the writer of a paper with the above title will be a warm advocate of the theory of specific germs in the etiology of disease, it would hardly be consistent for him to evolve a little germ for each of the three diseases from the same ultimate elements, even for the sake of effect.

I do not wish to be understood as disparaging or discrediting the immense value which the microscope has been, and still is, to scientific medical research, but it is well enough to remember that any valuable acquisition is easily and frequently overvalued by enthusiasts.

The presence in the air of minute organisms has been known for years. A century since, when the microscope was a mere plaything, Goethe in his inimitable work "*Faust*," made Mephistopheles say, "from air, water, earth, in wet, dry, hot, cold, germs by thousands evolve themselves, had I not reserved fire, I should have nothing apart for myself." The air is pregnant with minute life, and it seems easy to comprehend that disease or its elements being present it might be diffused by these floating particles without creating separate germs for the sole purpose of evolving or transporting each disorder.

According to the germ theory of disease a different form of bacteria, considered from a morphological standpoint, is essential to the causation of each disease of known bacterial origin. The three divisions of bacteria are, micrococcus, the granular forms; bacillus, rod-like in appearance, and spirillum which exists in the form of twisted threads, and is not conclusively proven to belong to the bacteria. Micrococcus is divided into many forms by the morphologist, as is also the bacillus, the mutability or stability of these different forms is not yet, however, thoroughly established.

In diphtheria, micrococci and bacilli are found in large numbers in the fauces, the former being the most constant in their appearance. Prof. Gradle, one of the latest writers on the germ theory, and an earnest advocate of its truths admits, however, that "*there is as yet no proof that these micrococci are the cause of the disease.*"² In fact experiments would seem to show that so far as known at the present time the presumptive evidence is all the other way.

In typhoid fever a bacillus has been found which has been held to play a part in causation, the most careful observers, however, have failed to find these bacilli in one-half of the cases of enteric fever examined. Koch was one of the observers, and he is probably the best bacillus hunter known at the present time, when we add to this the fact that in no well authenticated case has inoculation experiment propagated the anatomical lesion of typhoid fever in any animal; we must admit that the bacilli causing this disorder have not yet been demonstrated.

¹ A paper read before the Iowa and Illinois Central District Medical Association, April 10, 1884. Published by request of the Association.

² The Germ Theory of Disease. P. 186, 1883.

In scarlatina both micrococci and bacilli abound in numbers, but no one has shown by experimental cultivation their relationship to the disease.

There are a few disorders in which the causal relationship of bacteria has been apparently proven, but our three diseases are not among the number.

This paper deals with its subject and deduces its conclusions from a purely clinical standpoint, and the bacterial etiology has been alluded to merely to show that there is at present nothing positively known to refute the results logically arrived at from clinical data.

But whatever our opinion of the germ theory may be we must, I think, admit that improper sanitation plays an important part in the etiology of diphtheria, typhoid fever and scarlatina.

I shall present some facts and adduce some examples which appear to me to support the proposition that these three disorders owe their origin to a common source, that the same nidus may cause at one time the evolution of one malady, and at another time of a different one. What the peculiar predisposing force consists of which favors the production of one disease in preference to another, it is impossible to say, although various hypotheses with pages of text to support them might easily be written.

EXAMPLE No. 1. In northwestern Pennsylvania at the source of a small stream whose waters ultimately mingle with the Susquehanna, fifteen miles from a sewer, in a narrow valley is situated a lumber camp. Each season for four years prior to 1882 one or more cases of typhoid fever have been developed in this camp. In 1881 four men contracted the disease from which one died. In 1882 there were no cases of fever but two men were brought out ill with diphtheria, previously there had not been a case of the kind in the camp and the patients had not been within fifteen miles of diphtheria within a year.

Situated among the health-giving hills away from all modern improvements, here we have two of the products of civilization showing themselves "without any outside help."

Around this building the ground is soaked with refuse from the kitchen thrown out the door and windows; within two rods in one direction are placed the stables; about the same distance in another course we find a stagnant pool containing decaying vegetable and some animal matter; going up stairs we see twenty bunks ranged along either side of the low loft, about one foot apart, with a passage way slightly over two feet wide down the center; in these twenty bunks forty men sleep every night with the most of their clothing on, and still they live, some of them.

EXAMPLE No. 2. Eight miles from Emporium in a different direction is situated another camp, also in a valley. The foreman, his wife and two children did live four years ago in a small house built for their accommodation a few rods below the camp; a babbling brook ran by the door and the house seemed pleasantly situated. In the summer of 1880 one of the children contracted scarlatina without having been away from home or having had visitors for three months. In the fall of the same year both had diphtheria, from which the youngest died. The following

spring the remaining child was taken with typhoid fever, and acting upon my suggestion the family moved to town; the girl recovered in three weeks and has since been well. The murmuring stream brought down with it much of the refuse from the camp above, and frequently overflowing its low banks, deposited a certain portion thereof in close proximity to the dwelling, which, surrounded by thick trees, was not in a favorable location for the mountain breezes to carry off the noxious vapors. The woods around the house containing decaying vegetation, would perhaps have some work to perform in the production of disease; tree trunks in all stages of decay, layer upon layer of decaying and decayed ferns, grasses and leaves, the accumulation of years, periodically soaked with water, would perhaps be liable to generate gases which would not be particularly conducive to human health. Be that as it may, the three diseases were developed there under these conditions.

EXAMPLE No. 3. Four miles from this last-mentioned locality lives a farmer with a wife and seven children. In 1880, four of the children had scarlet fever; in the summer of 1881 one of the children had typhoid fever; in the fall of the same year the oldest child, a girl of 16 years, contracted typhoid fever from which she died. Three months later one of the children who had not had scarlatina took it, and two months later one of the others was taken with diphtheria.

The house is situated on rising ground, the water supply is apparently pure, and the surroundings are in good sanitary condition. I had no idea there was a cellar under the house, as no indications of one were visible. However, after the last case I made an inquiry which I should have made long before, and found not a cellar, but a pit underneath the dwelling, ingress to which was through a trap-door from the kitchen, merely a hole dug in the ground and sided up with hemlock boards decaying from the moisture. No ventilation was possible, and although it was comparatively clean as such holes go, yet used as a place of storage for vegetables, its atmosphere was necessarily far from salubrious.

I pointed out the danger and advised Mr. C. to fill up the hole, and my advice was acted upon; this was in the spring of 1882, since which time there has been no sickness in the house.

EXAMPLE No. 4. Down a valley eight miles distant stands a saw-mill surrounded by laborers' dwellings. Usually one or more cases of typhoid fever are developed in this valley each season; during the year of 1882, however, there were no such cases, but in December and January following, diphtheria was prevalent in the neighborhood of the mill, 30 cases occurring during that time, with a mortality of six. About two months later scarlatina in a mild form made its appearance and continued several months.

The first case of diphtheria occurred in a house where I could discover no sanitary irregularities, but this house was only a few rods from another habitation where the next six cases occurred two days later, and the condition of this latter was such that I cannot hesitate to believe that the first case was caused

by contiguity to it. If diphtheria or scarlatina were imported into this locality they were brought in a very clandestine manner, and the carrier was extremely careful to drop no seeds on the way, as the two diseases were confined to this small area, about two miles long by one-half mile wide.

EXAMPLE NO. 5. A valley nine miles long reaches out nearly at right angles to the one just mentioned. There have been in this valley one or more cases of typhoid fever every year for twelve years prior to 1882, during which season there did not occur one case. In September, 1882, however, diphtheria broke out to the extent of 15 cases with 4 deaths. The disease in this instance made its appearance eight miles up the valley, in a house where the cellar was in a filthy condition from decaying vegetables and stagnant water; the force of the endemic was expended on a few families in this immediate locality. It is a fact worthy of note that there were no cases of typhoid fever in this valley in 1882 for the first season in 12 years; and that the evolution of diphtheria evidently consumed the material which under other subtle conditions would have been used in the production of fever. In neither of the examples adduced was the outbreak of diphtheria general enough in character to explain the absence of fever by saying that most of the people having one disease, they therefore enjoyed immunity from the other. In the valley just alluded to typhoid fever again put in an appearance in 1883.

Judging from these cases, I cannot arrive logically at any other conclusion than that these three diseases are originally caused by disregard of the laws of hygiene. Their spread after development is another question entirely, and one with which we have at the present time no concern more than to venture the remark that the innocent inevitably suffer with the guilty; the persons whose doors are kept clean suffer the penalty of allowing their neighbors to live in ignorance of plain sanitary laws. If improper sanitation is the primordial factor in the evolution of these disorders, then it is not so important to ascertain in just what form and by what means disease is disseminated, as it is to strike at the root of the evil, to annihilate the first cause, without which there can be no elements of disease to be carried about by the air, by innocent micro-organisms, or by distinct varieties of minute life created for this especial purpose. As practical physicians, it is not a matter of great clinical importance whether or no bacteria are really the causes of these diseases and filth the nidus for their development. No remedy is known which will kill bacteria in the system without killing the patient, but we can remove in some cases the causes of ill health, whether it is really due to bacteria or not. Some people can be taught the danger of unsanitary surroundings, but many more will learn only when compelled to do so. The physician can instruct to a certain extent, but his advice would have much more weight if it was known that compulsion might follow its disregard.

The only body to successfully manage the education of the masses on this subject would be a carefully organized Board of Health with practically unlim-

ited power. When every town and hamlet has a health officer properly qualified and not afraid to do his duty, then will most diseases be lessened in severity, and in all probability some will disappear entirely.

A CASE OF URETHRAL ECTASIA.

BY C. C. FITE, M.D., NASHVILLE, TENN.

The description of a case of urethral ectasia or vaginal urethrocele by Professor Santesson in the *Nordiskt Medicinskt Arkiv*, which you reprint in the Aug. 16 number of the JOURNAL prompts me to report a case of the same kind I saw in March of this year. I did not know that the condition was so rare or I would have put it on record at the time.

I had been engaged to treat Mollie H. for what she designated "Womb disease," and in making the necessary examination to ascertain the position and condition of the parts, I made the following discovery. In passing the finger a tumor was felt just under the urethral orifice, and she said at once, "There it is, that is the trouble, it don't hurt much to pass it or to have intercourse, but it pains me in walking and when I make water, and sometimes it takes a long time to pass it, and occasionally it dribbles away of itself."

Upon more careful inquiry she admitted that coitus was painful, unless they were careful, but as she was very fond of that amusement she tried to make no complaint.

She is a muscular, ordinarily healthy white woman 24 years of age; married at 15, has had two children, one born 10 months after marriage, and the second in 13 months from the first; has miscarried twice, about the third month, since that time. She had difficult labor with both children, but got through without instrumental interference. After the second birth she says she had "inflammation of the womb, and of the bladder, and the milk dried up."

There is no history of any other severe illness or disease of any kind.

She had been instructed to retain her urine for some hours before the examination, as I find it sometimes of value to examine with a full bladder, and then after it is emptied. A silver catheter was passed and went readily into the bladder, and on being partially withdrawn the point was turned down, and the nature of the trouble was clearly demonstrated. The catheter was again passed to the bladder, and the contents withdrawn. When the instrument was being released from the meatus she complained of a sharp burning pain which lasted some minutes, she said that it always pained her so after urination.

I was satisfied at once of the nature of the case, and explained that the uterus needed no special treatment (having used a modification of the Sims speculum, and completed the usual explorations and found only a slightly enlarged and heavy organ), and advised an operation to reduce the size of the distended canal.

She was opposed to this and would not consent to operative measures, but was "willing to have medicine put on it," so I made three applications a week apart, of a 20 gr. solution of nit. silver, to the relaxed membranes covering the sacky canal.

After the applications the vagina and vulva were packed with absorbent cotton which was retained six hours. I also ordered injections of claret and tannin, $\mathfrak{D}\text{i}$ to $\mathfrak{f}\mathfrak{z}\text{viii}$, twice daily. She reported herself as well two weeks after the last application, but as she is now living elsewhere I have not been able to verify the statement. I explained to her that the cure was likely to be only temporary, and that an operation would doubtless be yet needed as the dilated canal had only been braced up and not organically reduced to its normal size. The trouble dated from the second labor, and I suppose the protracted pressure of the foetal head against the urethra must have caused the relaxation of its fibre.

MEDICAL PROGRESS.

SURGERY.

THE TREATMENT OF EPILEPTIFORM NEURALGIA.—Mr. W. J. Walsham (*Practitioner*) describes this disease as characterized by neuralgic paroxysms occurring in one or more branches of the fifth nerve, and always confined to one side of the face. The pain seldom lasts more than half a minute; begins at one spot, thence centrally spreads along that branch, and is radiated to the other branches of that division; or it may be transmitted to a second, or even to a third division of the fifth. A paroxysm may be determined by very various causes—speaking, eating, washing the face, a draught of cold air, a sudden noise, pressure on a certain spot, a fly settling on the beard—in short, anything, even of the most trifling nature.

In the treatment, nothing but nerve-stretching proved effectual. In the first case the infra-orbital nerve was stretched. The neuralgia was of ten years' duration, and for two years the patient was bed ridden on account of it. Three years after the operation she continued perfectly relieved. The second case was of nine years' duration, and the auriculo-temporal and inferior dental nerves were stretched, with complete relief to pain. The third case was one of relief from stretching the inferior dental, as with the fourth and fifth, the latter being a man 73 years of age, who had no bad symptom. The sixth case was a man 59 years of age, who had suffered for upwards of fourteen years, and had had the supra-orbital and infra-orbital stretched on various occasions. It was found impossible, from the matting of the tissues, to stretch them again. On careful examination it was determined that the pain really began in the gums in the region of the molar teeth, *i. e.*, in the posterior dental nerves, and shot upwards towards the back of the orbit. Meckel's ganglion and the whole of the superior maxillary nerve, from the foramen rotundum

to where it emerges upon the cheek, were removed. There was no bad symptom, and there was no recurrence of the pain.

As to the operation itself, the modes of stretching the supra and infra-orbital nerves are well known. The inferior dental, Mr. Walsham thinks, is best exposed from within the mouth. The mouth having been opened by a gag, an incision through the mucous membrane only is made from the last molar tooth in the upper jaw to the last molar tooth in the lower. The finger is now introduced into the wound and insinuated between the ascending ramus of the jaw and the internal pterygoid muscle. The small spur-like projection of bone at the entrance of the inferior dental canal is next felt for, and serves as a guide to the nerve. An aneurism needle with a very short curve is now passed and hooked round the nerve, which can then be drawn visibly into the entrance of the wound. There are no important structures with the exception of the inferior dental artery and gustatory nerve in the near neighborhood. The latter is best avoided by remembering that whilst the inferior dental nerve passes into the bone the gustatory continues its course between the bone and the muscle, and is anterior and a little internal in its relative position to the inferior dental. Should the artery be wounded, it will probably be torn rather than cut, and therefore not likely to bleed, were it to do so, it is doubtful whether it could be tied.

The internal lateral ligament which is inserted into the spur-like process of bone, follows somewhat the same course as the nerve and may be mistaken for it. To avoid it the point of the aneurism needle should be made to hitch in the entrance of the canal, and thence swept upwards, backwards and outwards around the nerve, keeping the point close to the bone. The wound, if the operation is neatly done, is small, and heals kindly and in a few days.

In stretching the auriculo-temporal nerve the best guide is the temporal artery. An incision about an inch long should be made parallel and immediately posterior to the artery, beginning at just above the zygoma. Having carefully exposed the artery, the nerve will be discovered just below and posterior to it. The nerve being of small size the dissection must be done neatly, or it will not be found.

MEDICINE.

INVESTIGATIONS INTO THE PATHOGENETIC MICROBIA OF BLENNORRHAGIA.—Edouard Welandér gives us in the *Nordiskt Medicinskt Arkiv* the results of his studies of the *gonococcus* as described by Neisser in 1879. These microbiae are easily stained by a solution of 1 to 2 per cent. of fuchsine, and they are easily obtained from the male urethra by pressing the glass against the meatus while expressing the pus with the fingers; with the female urethra it is not so easy, here the end of a canulated sound is introduced and pressed against the walls of the urethra while removing it.

The gonococci are colored a blackish brown by the fuchsine, the nuclei giving an intense red, and the

protoplasm a light red. They are found almost always in groups, never in chaplets, as often in the interior as external to pus cells, frequently in large groups about the epithelial cells, and sometimes free.

The writer has found them in 129 cases of acute blennorrhagia and 15 cases of chronic blennorrhagia in the male, and in 79 cases of purulent urethral secretion in the female, but has not found them in other secretions. In 25 cases of blennorrhagia (with gonococci) he was able to discover the persons who communicated the contagion and to find in them also the presence of the gonococci.

The attempts at inoculation with the secretions not containing the gonococci gave negative results. In 5 cases the secretion from fetid balanitis was introduced into the urethra, this secretion, which contained minute bacilliform microbiæ, did not have the slightest effect. The vaginal secretion charged with microbiæ of numerous different forms was similarly inoculated without effect.

In the urethræ of three men the vaginal secretion from a virgin 14 years of age was introduced. The secretion contained epithelial cells, spherical and bacilliform microbiæ—no result. A fetid and purulent secretion from the vagina, which contained a large quantity of bacilliform microbiæ with very active movement was introduced into the urethræ of 3 men without. In 3 women where the urethral secretion contained the gonococci, but the vaginal secretion was free from it, a considerable quantity of the vaginal secretion was introduced into the urethræ of 3 men without effect. One of these women was menstruating. At the same time there was taken from this woman a very small quantity of the urethral secretion containing the gonococci and introduced into the urethra of a man, with the result that at the end of 2 days there was a urethral discharge from the urethra containing the gonococci with epithelial cells, and on the 3rd day he had blennorrhagia with great masses of the gonococci. An identical result was produced by the inoculation of the urethral secretion of the two other women. A small quantity of the urethral secretion containing the gonococci produced a blennorrhagia in the same subjects in whom it had been possible to introduce a large quantity of the vaginal secretion, free from gonococci, of these same women without results.

While these results are strongly in favor of the pathogenetic nature of the gonococci, they do not furnish the scientific proof of their nature. To establish that it will be necessary to cultivate and inoculate these microbiæ, which cultivation is very difficult, and they cannot be inoculated upon the lower animals.

Welander found the gonococcus in men not only in the urethral secretion, but also, in 4 cases, in periurethral abscess, once in a lymphangitis which had been converted into an abscess, and where the purulent secretion, of several months' duration, from the extremity of the lymphatic cord contained the gonococci.

The presence of the gonococcus in the vagina was only determined 10 times; in 4 cases the vaginitis was acute, in all the others, subacute with purulent

secretion. The cervical secretion, which was more or less purulent, was frequently examined in prostitutes, without showing the gonococci. But of 163 women—not selected, in 79 gonococci were found in the urethral secretion.

The clear secretion from the glands of Bartholin was examined in twelve cases. No gonococci were found, but other microbiæ were present. In 5 cases of acute bartholinitis no gonococci were found, although 3 of the women had them in their urethræ. In two women suffering from fistula the result of bartholinitis, gonococci were found in the secretion coming from the fistulæ, they also had gonococci in the urethræ. In 21 women who suffered from a purulent discharge from the excretory canal of the gland of Bartholin, the gonococci were found in each case. All these women except one had these microbiæ in their urethræ. The fact that the gonococci are frequently found in the gland of Bartholin and in its excretory duct, is of great practical importance. This makes the possibility a very strong one that a woman suffering from this affection would communicate blennorrhagia in coitus—while a woman who has the gonococci in small quantity in the urethral secretion is much less dangerous.

CANCER OF THE PANCREAS.—M. Babbillon reports (*Le Progrès Médical*) a case of cancer of the pancreas in a man who was in a state of extreme emaciation and suffered from cough for two years, but for three months before death he had a gradually increasing difficulty in retaining food in the stomach; there was no vomiting, but an almost immediate regurgitation of the food taken. Habitual constipation, retracted abdomen, epigastric region painful to the touch, with a doughy feel. Other symptoms negative.

The autopsy showed tuberculous deposits at the summit of both lungs. There was a vast aneurismal dilatation at the arch of the aorta, which was dilated throughout its thoracic portion and full of stratified clots. At the epigastrium was a carcinomatous mass as large as the fist and developed at the expense of and about the stomach. It was immediately to the left of the cardiac orifice, and had invaded the lymphatic ganglia. The pancreas was stuffed with carcinomatous deposits, of which one, that was quite voluminous, when cut into gave out a puriform fluid. There was also a lobulated cyst at the inferior border of the pancreas.

This case is of interest in several respects: In the first place, the aortic aneurism remained entirely unrecognized during the lifetime of the patient; probably the dilatation of the thoracic aorta, which ceased suddenly at the diaphragm, was in part due to the compression exercised on it by the carcinomatous abdominal mass. Secondly, by the absence of all vomiting and the existence of alimentary regurgitation, which allowed of a diagnosis locating the cancer at or near the cardiac orifice of the stomach; and thirdly, the presence of cystic and carcinomatous degeneration of the stomach without any glycosuria during life.

THE
Journal of the American Medical Association.
PUBLISHED WEEKLY.

THE EDITOR of this JOURNAL would be glad to receive any items of general interest in regard to local events, or matters that it is desirable to call to the attention of the profession. Letters written for publication or containing items of information, should be accompanied by the writer's full name and address, although not necessarily to be published. All communications in regard to editorial work should be addressed to the Editor

SUBSCRIPTION PRICE, INCLUDING POSTAGE.

PER ANNUM, IN ADVANCE..... \$5.00.

SINGLE COPIES..... 10 CENTS.

Subscriptions may begin at any date. The safest mode of remittance is by bank check or postal money order, drawn to the order of the undersigned. When neither is accessible, remittances may be made at the risk of the publishers, by forwarding in REGISTERED letters.

JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION,
No. 65 RANDOLPH STREET,
CHICAGO, ILLINOIS

SATURDAY, AUGUST 30, 1884.

GASTRIC DILATATION.—At a recent meeting of the Société Médicale des Hôpitaux, M. Bouchard gave some interesting conclusions based on an analysis of 220 cases of dilatation of the stomach. As he found that it is associated with chronic disorders in sixty per cent. of the cases, it is but natural that it should often be masked by a variety of symptoms pertaining to the concomitant disease. It is the more apt to be overlooked, since it is not always manifested by dyspeptic disturbances. M. Bouchard divides ectasis of the stomach into "enteric, dyspeptic, hepatic, renal, cardiac, cutaneous, rheumatic, consumptive," according to the prominence of the phenomena. Furthermore, he regards the disorders, which are expressed by these diverse groups of symptoms and which complicate the malady in question, as its result, though the connecting link is not always easy of discovery. That dilatation of the stomach may lead to many of these conditions, particularly dyspeptic, enteric, cutaneous, etc., is not unreasonable; but it seems to us somewhat injudicious to attribute "cardiac lesions," unless indeed they be functional, to gastric distention. In the abstract of his paper, which alone we have seen, the nature of the lesions which he designates "cardiac," whether organic or inorganic, is not stated, but, if he means the latter, we have no desire to dispute him. On the other hand, if he refer to organic heart disease, may he not have committed the fatal error of confounding it with an accidental concomitant or of mistaking cause for effect. A recognized result of heart disease, in particular of mitral lesion, is congestion of the ab-

dominal viscera; and in the case of the stomach, this is sooner or later manifested by impaired digestion. The food undergoes fermentation, fatty acids are evolved, and the patient suffers from distressing flatulence and eructations. If this evolution of flatus continues in this distensible organ day after day, as it must inevitably do, gastric dilatation would be a natural consequence. Hence, contrary to Bouchard's statement, a dyspepsia, itself the effect of a cardiac lesion, would cause the dilatation, and not the latter cause the indigestion. However this may be, we fail to appreciate how distention of the stomach can do more than functionally derange the heart.

The diagnosis of this stomachic disorder is determined, according to Bouchard, by the detection of a "*bruit de clapotement*," a succussion sound upon percussing the organ below an imaginary line connecting the last rib of the left side with the umbilicus.

Dujardin-Beaumetz criticised this justly as being scarcely reliable, even if practiced after a state of fasting or the ingestion of liquids. Ziemssen, who enjoys a great opportunity for the study of this condition among the inordinate beer-drinkers of Munich, where it is of frequent occurrence (though we do not mean to trace a connection between it and the habitual consumption of a large quantity of beer) says the only absolute method of determining ectasis of the stomach is to distend the organ by means of carbonic acid and then outline it before the gas escapes. This is easily accomplished by administering separately bicarbonate of soda and tartaric acid in solution. Thus distended the stomach emits a highly sonorous percussion note and can be easily outlined. Indeed, in marked cases the organ can often be seen as a huge tumor which then does not even need to be percussed. This procedure occasions the patient some temporary discomfort, and after a few minutes, the ejection of the contents of the stomach, but is entirely harmless.

IRRIGATION AND EPURATION OF SEWERAGE.—We make no apology for having occupied a part of the space allotted to proceedings of medical societies in several preceding numbers of the JOURNAL, with the very interesting and important paper of Dr. Barnes and the discussion thereon in the Section on Practice of Medicine and Hygiene of the Suffolk District Medical Society, Mass. The subject there discussed, namely, how best to dispose of the excretions and refuse necessarily accompanying the aggregation of human beings into families and communities of fixed location, is perhaps the most important of all the sanitary problems that are now demanding the atten-

tion of the profession. The progress of civilization has demonstrated no one thing more clearly, than that soil and water contaminated by the presence in them of such excretory and refuse matter, are capable of engendering several of the most distressing and fatal diseases we have to encounter. And yet such contamination has commenced, and is progressively increasing wherever the excretions and refuse are either deposited in cesspools, sunk in the soil, or turned through sewers into the neighboring waters, whether of brook, river, lake, or sea. The evil has chiefly attracted attention in connection with the sewerage of cities and manufacturing towns, but it exists to a greater or less degree wherever human beings become permanent residents.

It would be easy to find thousands of isolated farm houses resting upon soil impregnated with the drippings of the kitchen, the cesspools, and the barnyard, and in which typhoid fever, diphtheria, scarlatina, etc., are almost annual visitors! [See the examples given by Dr. Bardwell in his paper in another part of this JOURNAL.] If it is true, as claimed by Dr. Barnes, that the only effectual mode of rendering sewerage material innocuous and preserving the purity of water and soil, is to use it for the irrigation of either forests or cultivated lands, where it is effectually epurated in nature's laboratory, and its materials appropriated for vegetable growth, the sooner the work is begun in that direction, both in cities and rural districts, the better it will be for human health, prosperity and life. It would be a comparatively easy task for a large proportion of our farmers and inhabitants of villages, to turn all the contents or drippings of the cesspools and barnyards, through drainage pipes to neighboring cultivated fields where it would increase the harvest in the very act of undergoing effectual epuration.

The subject is worthy of a large share of the attention of the American Public Health Association at its meeting in St. Louis the approaching autumn. For, say what we please about the seeds or germs of disease and the laws of their diffusion, it is certain that none of them thrive well in pure air accompanied by pure water and a clean soil.

INTERNATIONAL MEDICAL CONGRESS.—The meeting of this organization at Copenhagen, having closed its sessions, is described by correspondents as having been highly satisfactory in all respects. The number in attendance was not so great as in London, three years previously; but the papers read and questions discussed were of general scientific interest and

practical value. The invitation given by the American Medical Association, through its delegates, to hold the next meeting of the Congress in Washington, in 1887, was accepted. And it will be both the duty and the pleasure of the profession in this country, to make such preparations as will render that meeting equal in all respects, if not superior, to the one held in London in 1881.

PROGRESS OF CHOLERA.—We have nothing new to record in regard to the progress of cholera in Europe. At latest dates no new cases had occurred in Geneva, and the advancement of the season renders it probable that the scourge will this year be limited mostly to its present boundaries. The early refugees from Toulon and Marseilles are returning in great destitution; and as the disease still exists in both cities, many of them will be likely to become its victims.

In a previous number it was noticed that the cholera had appeared on a vessel bound for St. Lucia and New York. The vessel was cleared of its sick and disinfected at its first stopping place, and has since arrived off the harbor of New York, and is reported to be without sickness, and in a good sanitary condition.

DR. JOSEPH JANVIER WOODWARD, Surgeon U. S. A., and one of the ex-Presidents of the American Medical Association, died on the 17th inst., of disease of the brain, from which he had been suffering during the last two years. His connection with the Army Medical Museum and the Medical History of the Rebellion, together with his high scientific attainments, had caused him to be widely known and highly esteemed by the profession, both at home and abroad.

For a more full and interesting biographical sketch of the deceased, we refer to the Necrological department of this number of the JOURNAL.

TRANSFUSION OF BLOOD.—Under the head of Medical Progress, on page 188 of No. 7, Vol. three, of the JOURNAL, in stating the quantity of blood transfused in the case under consideration, the writer gives the expression "215 grammes (37 fl. oz.)." Of course, 7 fl. oz. are meant, instead of 37.

PRESIDENT OF THE BRITISH MEDICAL ASSOCIATION.—At the recent meeting of the Association in Belfast, Dr. W. T. Edwards, of Cardiff, was elected President for the ensuing year, and that city selected as the place for holding the next annual meeting.

THE American Association for the Advancement of Science is to hold its next meeting in Philadelphia, commencing Sept. 4, 1884. A large number of the members of the British Association are expected to be present.

RESIGNATION.—Dr. John C. Fisher, one of the most prominent members of the Marine Hospital Service, has tendered his resignation to take effect Sept. 30, 1884.

SOCIETY PROCEEDINGS.

CHICAGO SOCIETY OF OPHTHALMOLOGY AND OTOTOLOGY.

APRIL 8, 1884.

Dr. Boyer was unanimously elected a member of the Society.

Dr. Holmes then referred to a case, in which he had recently removed a splinter of steel from the vitreous humor by means of a Gruening's magnet. The incision in the sclerotic, through which the magnet was introduced, was made behind the ciliary region, in the temporal portion of the globe, although the foreign body could be seen lying in the vitreous, near the equatorial region of the opposite hemisphere.

The lens was so far cataractous that the metal could not be precisely located, either by oblique illumination or by the ophthalmoscope. Dr. Holmes believed the end of the magnetized probe could in this way be brought near the steel with less violence to the edges of the wound of the sclerotic, choroid and retina, than if the wound had been made in the nasal portion of the globe. In a case in which the lens being intact, the metal could be exactly located, it would be desirable to introduce the magnet as near the foreign body as possible, although the reporter thought there is liable to be more hæmorrhage from the conjunctiva at the inner than at the external angle.

The doctor thought that a crucial incision through the sclerotic, although advised, is objectionable, and called for the opinion of the Society as to the relative advantage of the various kinds of incision.

Dr. E. Z. Gardiner thought a crucial incision would expose the eye to greater danger than a long linear incision, in the latter case there being but two instead of four flaps.

Dr. Montgomery expressed a similar opinion.

Dr. F. C. Hotz also advocated the linear incision where the other was not an absolute necessity, and in this connection reported the following case:

Piece of Steel in Vitreous. August 29, 1882, I removed a piece of steel from the vitreous chamber with Gruening's magnet, under conditions which proved a very good result as to the preservation of the sight. The steel entered through the sclerotic on the previous evening. Except the minute cut on the sclerotic six millimetres from the nasal border of the

cornea, there was nothing abnormal with the eye. With the ophthalmoscope a lanceolated body was discovered suspended in the vitreous, just above and behind the centre, it presented a bright, shining, silvery surface, and looked very much in shape as a diminutive silver fish turned downwards. A few dark streaks extended from the body to the sclerotic wound; otherwise the vitreous was clear. The fundus showed no lesion. The sight, I am sorry to say, was not tested. Under chloroform the scleral wound was enlarged horizontally to $2\frac{1}{2}$ millimetres. The edges were held apart with fine hooks. Gruening's magnet introduced, on the first attempt the steel was brought out. It was 6 millimetres long, $1\frac{1}{2}$ millimetres broad, tapering off to sharp points, and weighed 20 milligrammes. The wound was closed up by a conjunctival suture, and the patient put to bed with both eyes bandaged. He was kept in bed in a dark room a whole week. No unfavorable reaction followed, but he could only count fingers at six feet. With the ophthalmoscope I discovered no disturbance in the vitreous, except two dark streaks from the wound to the centre, and an opaque transverse streak in the fundus, above the papilla. During the second week the lower portion of the vitreous became very cloudy, and the opaque stripe in the fundus developed into a distinct retinal detached fold.

Later the obscuration of the vitreous consolidated into several separate clouds, between which portions of the fundus could be seen. Some parts of it appeared normal; in some the retina was distinctly detached, and in some it seemed that the retina was separated from the choroid by a thin layer of serum.

The patient was under observation three months. No material changes took place, and the sight did not improve.

Dr. E. Z. Gardiner then read a paper entitled Detachment of the Retina.

After reporting a case of extensive detachment of the retina, in which total re-application of the detached membrane took place, remaining *in situ* for two weeks, and then, without any perceptible cause, becoming detached again, the lecturer said:

The literature on the etiology of detachment of the retina is so extensive that the scope of this paper will not permit me to mention all that has been written on the subject, but I will endeavor to record with the extension that they deserve the theories which now seem to be most in favor.

For the sake of clearness, these theories may be divided into three groups:

The authors whose theories are comprised in the first group, claim that it is a fluid secreted by the choroid which, accumulating under the retina, produces the detachment.

Those comprised in the second, that a lack of elasticity in the retina as compared with the choroid and sclerotic, is the immediate cause.

In the third group are those who look on a shrinkage of the vitreous as the direct cause of detachment.

Among the latest articles on this subject I will mention that of Prof. Kara, who thinks that in a partial elongation of the choroid a distention of its elastic layer, and also of its hexagonal epithelium, takes

place. The sclerotic also becomes thinned, at this portion of the globe. This thinning of the membranes favors, according to him, the filtration of the lymph contained in Schwalbe's spaces, and facilitates its accumulation between the choroid and the retina.

Boucheron, in a recent communication to the Congress of Rouen, introduces in the pathogenesis of the retina, the latest theories advanced by the physiologists about the secretion of the intraocular liquids. He claims that the choroidal epithelium is the secreting element. When this secretion is excessive, it accumulates behind the retina and detachment is produced. As causes of this hypersecretion he mentions affections of the kidneys, rheumatism, etc.

Dr. Galezowski, in an exhaustive article published in the *Recueil D'Ophthalmologie*, claims that a circumscribed choroido-cyclitis is the cause of detachment, but that a previous liquefaction of the vitreous must necessarily exist, before a detachment takes place. To prove his theory (advanced first in 1873), he reports several interesting cases, and then appends a very instructive table of 649 cases—of these, 598 happened in myopic eyes; 51 in cases of hypermetropia and emmetropia. In 131 cases only could a rent be detected in the retina. In 120 he observed floating opacities in the vitreous. This author thinks that the presence of floating opacities in the vitreous is a sign of perforation and tearing of the retina.

Of those who look on the pathological changes of the vitreous humor as the direct cause of detachment of the retina, Henri Muller should be first mentioned. In 1866 he made the assertion that in certain cases detachment of the retina was caused by shrinkage of the vitreous. Previous to this date, however, he had called attention to the fact of the vitreous possessing the property of diminishing in volume, through a process of shrinkage which could end in a detachment of this humor from the retina. The first histological investigations in this interesting phenomenon were made by Ivanhoff. Prof. Leber read before the Ophthalmological Congress at Heidelberg (1882) a very instructive paper, in which he explains the detachment of the retina by the so-called perforation theory. By this theory, the frequent phenomenon of sudden detachment of the retina without a perceptible change in the tension of the ball, is explained. The primary cause of the detachment is a localized alteration of the vitreous in contact with the retina, consisting in hypertrophy of the radial fibres, formation of fine bundles of connective tissue, which in the process of contraction exert a traction upon the retina, which produces a solution of continuity in the membrane, thus allowing the degenerated and liquefied vitreous to pass between it and the choroid. In this process there is simply a change of locality of the fluid from the inner side to its outer—consequently there is no cause for an increase of tension.

Leber bases his theory upon the evidence brought to light by the examination of 27 cases of detachment, seen by him during the last two years, of these 15 were "fresh" cases, from a few days to two weeks duration. In 11 of these a perforation was demonstrated, in one it was suspected, while in the remaining three its existence could not be proven,

neither excluded. In long-standing cases perforations were not seen as often. In 12 cases, lasting from ten months to ten years, a perforation was found only in 3 cases. In 4 its existence seemed very probable—not found in five cases. Summing up the 27 cases, a positive result was reached in 14—doubtful in 4—negative 8. We have now reviewed in a succinct manner the theories advanced to explain the causes of a disease with which we are unfortunately too familiar. But wherein lies the truth, is hard to tell. All the theories are made so plausible, by their propounders, that one is tempted to accept them as the truth and turn away from that uncomfortable state of mind which to uncertainty is inherent. But unexpectedly some clinical fact jumps into the field and overturns the whole theoretical structure, leaving us in the same perplexing situation from which we started. The truth is, although it may pain us to confess it, that the etiology of detachment of the retina in myopic eyes, still remains shrouded in mystery.

In the selection of a theory we should be guided entirely by clinical experience, for I believe that a clinical fact is worth more than a hundred theories. Experimentation is worth but little in this line of investigation, because the process to which an eye has to be submitted in order to bring about the condition which we find present in highly myopic eyes, is such that it renders the results untrustworthy. We know that foreign bodies thrust into the eye experimentally or accidentally will, through a process of inflammation and subsequent shrinkage of the vitreous, detach the retina, but this fact cannot explain the cause of detachment in myopic eyes where absolutely no traumatism has existed. I performed a number of experiments in pigs' eyes, but here also the results were unreliable, not only on account of the post-mortem changes which had taken place, but also because the condition of the vitreous is entirely different from that found in highly myopic eyes, and in attempting to render it liquid, or withdraw a portion of it, or inject, or rather attempt to inject, fluid under the retina so much traumatism is necessary that reliable results are nearly impossible. Experiments may and do cast a little light upon the matter, but it is not sufficient to enable us to draw any positive deduction therefrom. Relying entirely on the clinical test, let us by its light examine these theories.

The theory of subretinal effusion can explain certain varieties of detachments of the retina, if a pre-existent diminution in the volume of the vitreous is admissible. In a gradual detachment this theory explains matters in a satisfactory manner. But in a sudden detachment, it does not. I can not conceive how a vitreous, partially liquefied or not, should, as if by magic, decrease sufficiently in volume, to allow another fluid to exude into a chamber limited by a resistant lining and to do this *without increasing at any time the tension*. This is contrary to all physical laws, and when we remember that the tension, far from being increased, is diminished, the conclusion forces itself upon our minds that we must look elsewhere for a more satisfactory explanation. We do not find it I think in Von Graefe's theory, in which

the trouble is ascribed to a lack of elasticity of the retina as compared to that of the choroid and of the sclerotic. This theory does not stand the clinical test, for how can we admit this lack of elasticity in a membrane which gives such strong evidences of the contrary in its inflammatory conditions. Let us now turn to the theory based upon the shrinkage of the vitreous as a cause of detachment of the retina. Before entering fully into the matter I will endeavor to explain the reason why the posterior portion of the vitreous in highly myopic eyes where sclerectasia posterior exists, is found to be in a fluid degenerated condition, and also why in such eyes there is a tendency to shrinkage of the vitreous.

The experiments performed by Max Kneis, show that the vitreous receives its nutrition from the choroid; the liquid lymph passing through the retina, the external layers of which it also nourishes. At the posterior pole, according to this author, the nutrition is very slight, owing to the greater thickness of the retina at this place. As the retina becomes thinner, the amount of fluid which passes into the vitreous is larger, and it reaches its maximum, at the most anterior portion of the choroid. Now if in the physiological condition the nutrition of the posterior pole is very meagre, it is but reasonable to deduct that if the choroid at this point is degenerated the nutrition will decrease in proportion to such degeneration, reaching at last a point where the secretion of lymph is so poor that it lacks the power to constitute healthy vitreous humor. In this manner the liquefaction of the vitreous at the posterior pole of highly myopic eyes mentioned by Alt is easily explained. But even if the theory of Max Kneis is not accepted and we admit that the vitreous receives its nutrition only from the anterior portion of the choroid, the ciliary body, then too if there is a lack of nutrition, the first part to suffer will be that further removed from the source of nutrition, in other words, that portion of the vitreous nearest the posterior pole. It is a fact that highly myopic eyes in which degeneration of the choroid or sclerectasia posterior is present, are not healthy, and the liquefaction of the vitreous is a proof in itself of the poor nutrition it has received, be its source from the ciliary body or from the whole choroid. The natural consequence of poor nutrition is shrinkage, diminution in volume, atrophy, etc. These premises once accepted, we find that Leber's theory will explain in a satisfactory manner the phenomena which take place in detachment of the retina, a shrinking vitreous in the anterior portion of which a radial formation exists, (Leber). The adhesions formed by a diseased vitreous, at those points where it is still in contact with the retina, a liquefaction of the vitreous beginning at the posterior pole and gradually advancing toward the anterior portion of the eye, are the immediate cause of the catastrophe which only needs one step more to take place. The traction on the retina increases as the shrinkage progresses, thus giving rise to the metamorphopsia and other prodromic symptoms. The continued traction or a sudden jar overcomes the resistance of the already strained retina; it tears, the liquefied vitreous enters behind the mem-

brane, and the detachment is effected. Dr. Galezowski, in his excellent article above referred to, states that he only found a rent in the retina in 131 cases, and that floating opacities were seen in but 120. He, therefore, claims that the presence of floating opacities in a case of detachment of the retina points to the existence of a rent in this membrane, and *vice versa*, that the absence of these opacities is a sign that no tearing has taken place. This statement does not bear the clinical test, however, for we all have seen cases where floating opacities in the vitreous long precede detachment of the retina. The simple fact that the rent could not be seen does not, in my opinion, prove that it did not exist, for it might well happen that it was so situated that it could not be seen—indeed, I believe that in many cases they escape notice because they are so located that the folds of the detached retina entirely hide it from view; and furthermore, it is not at all necessary for the solution of continuity to be large. The retina tears in a manner very similar to thoroughly soaked blotting-paper, as I have been able to convince myself by tearing the fresh retina under the microscope. There is a moment before the regular separation of parts takes place when a liquid can easily penetrate through it, and as the moment that the retina becomes detached the traction from the vitreous ceases, the rent may remain stationary and not acquire such proportions as to render it visible with the ophthalmoscope. I do not consider the case which the same author reports; in which a small opacity was seen engaged in a perforated retina, working its way into the vitreous, as a proof that the opacities are formed only in the subretinal fluid. There is another form of detachment of the retina, the etiology of which is made by the theory of shrinkage of the vitreous, viz.: detachment in folds. In this form the subretinal effusion theory utterly fails, for a liquid secreted under a membrane which is equally throughout would naturally expand in a circular form. The detachment would, therefore, commence at the centre of the figure and gradually creep on to the periphery. On the other hand, nothing is easier to account for than a fold being raised by a traction exerted from within. The process can be easily demonstrated, even in eyes where the vitreous is not degenerated, by introducing a very fine pair of forceps into the vitreous chamber, firmly closing them and gently withdrawing them. In this manner I have been able to produce beautiful specimens of detachment in folds. I am perfectly aware that this theory does not answer in every case, and the clinical history of certain cases will militate against it; but I firmly believe that in those cases of detachment of the retina happening in highly myopic eyes, the immediate cause is the traction exerted by a degenerated and shrinking vitreous, and no other theory that I know of can explain in a rational manner one of its most constant phenomena, viz., the suddenness of the detachment. Neither can any of the other theories explain in a rational manner how there can exist a fluid behind and another in front of the retina, without a perceptible increase of tension.

This paper called forth a long discussion on the merits of pilocarpine treatment. Almost every mem-

ber had given this remedy a trial, and all were unanimous as to its inefficacy in producing a permanent cure.

Dr. Montgomery exhibited a new self-registering perimeter, by M. Blitz (Upsala). It is fixed to the back of the chair in which the patient sits. The test object is carried by a bent arm coming from behind, and is suspended before the patient's eye.¹

BOERNE BETTMAN, Sec'y.

CHICAGO MEDICAL SOCIETY.

A THEORY OF THE CHOLERA.

A paper read before the Chicago Medical Society, August 18, 1884. By John Bartlett, M.D., Chicago, Ill.²

MR. PRESIDENT :

At the last meeting of this Society, in referring to the cause of cholera, its methods of advance, mode of spread, etc., it was manifest that a radical difference of opinion prevailed as to these features of the disease. While it must be admitted that the knowledge of the cholera is very imperfect, it may yet be of interest and profit to frame some theory of the disease which shall conform to every known fact regarding it, and which may offer explanations of the phenomena of the disorder as satisfactory as the limited knowledge of such subjects will in the present state of science admit of. Such a theory is of value, if simply as a framework which may hold together in an apparently perfect order and relation, a large number of fragmentary facts which might be lost to the mind if allowed to lie detached and disconnected.

I have accordingly presumed to set before you to-night what I conceive to be, such a theory of the disease, taking occasion to follow the method of induction so far as to erect the theory upon a trestle work of facts, assumed to be analogous, drawn from other departments of observation.

Events are occurring about us similar in many particulars to the rise and spread of epidemic diseases. One of the most striking of these, perhaps, is the prevalence of that plague to vegetation, the army worm. The laws of this pest have something in common with those of cholera. Thus the cause of the army worm is always present in, and indigenous to, certain localities favorable to its development, life and methods of propagation. Appearing yearly in these habitats it spreads occasionally, and with some show of periodicity over extents of territory far beyond its normal limits; and these periodic eruptions frequently cover vast areas of territory, carrying devastation over continents. In this march outward from the nidus of development, pushing onward, and further onward, by somewhat regular, yet occasion-

ally interrupted stages, the army worm resembles an epidemic of disease in its mode of approach to a place, its gradual attainment of an acme of destructiveness, and final abatement. Thus the army worm millers indigenous to certain marshy lands of the South, in the year 1861, sallied from their haunts in illimitable swarms and deposited their eggs in suitable places and at a suitable period of the growth of early vegetation in every county from the Gulf to the Lakes. These eggs lay dormant until stimulated by the warm weather. Then, apparently, starting from its habitat at the southward, began the northward march of the army worm which overran the country. It was because of the fact of the apparent onward march of the countless hosts of these invaders that they received the suggestive name of the "Army Worm." And yet their march was only apparent. They moved only from field to field, as other insects for the purpose of forage. They advanced northward only as the peach blossom advances northward, their march kept pace with the increment of heat of the advancing season necessary for the development of the long-deposited egg. The line of their advance was an isothermal one.

Thus the worms keeping pace with vegetation, appearing when the winter wheat was "in the milk," advanced toward the north slowly, so that they appeared in Maine two months after they were first seen in Missouri. After several weeks the destroying agents disappeared. They had not moved on to other conquests, as people supposed, but the worm, disappearing under the sod, had become a chrysalis, which in a few weeks emitted the miller, which deposited its eggs, and thus completed the cycle of the insect's life. In the above reference to the army worm invasion it was assumed by some that the whole field devastated had been sown with the germ of the plague the previous season. Observation of the insect indicated, however, that it passed through its phases within a few weeks; and it is probable that the visitation was not thus sown broad-cast and at one time; but that the invasion was by the gradual encroachments of successive "crops" of the worm; so that the insects marching northward into Michigan were not "cotemporaries," but the descendants by several removes of those which weeks before invaded Southern Illinois. Thus a brood of worms, disappearing in the northern counties of Mississippi as chrysalites, were represented in a few weeks in Middle Tennessee by millers attracted northward in search of early vegetation suitable as nidi for their eggs. The crop of moths from these eggs would in turn deposit their ova in Kentucky, and so the advance northward would be effected not by the worms, but by that element of the insect floating in the air and endowed with power of swift flight, and with selective instinct. In regard to the continuance of the recurrence of these insects it is essential that the several elements find suitable resting surfaces and conditions (of temperature, moisture, etc.), and in the lack of these the element may perish, or may remain inactive for an indefinite period, till conditions occur requisite to arouse it to development. Thus in the latitude of St. Louis, with favorable conditions two

¹For a more detailed description, we refer the reader to the *Centralblatt für prakt. Augenheilk.*, August, 1882, p. 251.

²The interesting paper of Dr. Bartlett herewith presented, will be read with more satisfaction and interest, if it be known that the illustrations made use of, "Army Worm" and the "Marsh Fungus," have been carefully studied in the field by him. As long ago as 1861 he wrote a paper on the "Army Worm," the first paper ever written and published. See Dr. Smith's (State Entomologist of New York) report 1861. The author's experience with the cholera has also been ample. And with this annotation, the paper is submitted to the editor of the JOURNAL for publication.
L. H. MONTGOMERY, M.D., Sec.

or three broods of the worm were hatched in one season, while in Maine a second brood did not appear. Injury to crops wrought by secondary broods in one locality was comparatively limited. The new worms were preyed upon largely by enemies now come into the field, and material suitable for their sustenance was scarce, in good measure exhausted by the depredations of their predecessors. Finally, the miller of the army worm, "winters over," and deposits its egg at the appearance of vegetation in the spring.

By accident or design the insect in any of its phases could be transported to any distance; and as a miller it might be readily carried by the wind.

Dr. Koch, the noted microscopical investigator of the causes of disease, believes that he has discovered the actual entity producing the cholera in a fungoid cell, the "comma bacillus." As yet no more is known of this bacillus than its bare existence. It has a natural history, but the laws of its development and changing growth are yet to be learned. In the absence of such knowledge we may assume that it has certain phases of development as the army worm has, and that in each one of these it presents different potentialities. In relation to certain fungoid cells, the fact of such phases of existence are ascertained, and from analogy it may be inferred that the comma bacillus, after a period of active growth, develops into an apparently lifeless formed material, a crystalline substance, bearing, for illustration we may say, the same relation to the cell as coral does to the insect which forms it. This crystalline substance is not dead but living matter, and after a period of passivity, under favoring circumstances it puts forth buds, which presently burst and emit into surrounding media a protoplasmic fluid in which in time are developed the cells, thus completing the cycle of changes in the life of the plant. The peculiarities of the several elements may be thus stated; the crystalline substance we may suppose, is in the form of dust, granules or threads, not an impalpable something, but a material which may be seen by the naked eye and handled by the fingers. Under the microscope it may be seen to form from an aggregation and concretion of the cells. From it buds sprouting emit what may be compared to the contents of an egg—a protoplasm—an apparently homogeneous aqueous fluid in which presently begin to appear dim outlines of cells that gradually grow in size and increase indefinitely, not from cell division, but from the development of a cell from every atom of the protoplasm. The power of this fluid is only exhausted when its ultimate atom has become a cell. The characters of the protoplasm prior to the development of cells would probably elude all efforts at recognition so that fluids and tissues of a body containing it might be examined with the highest powers of the microscope without the detection of any organic particles.

All parts of the cholera fungus then are portable, all are tangible, visible entities, except the infinitely minute atoms of cells in the protoplasm.

The entrance of this fluid into the economy impregnates the system with the ultimate germ of the cells which under favoring circumstances develops at

the expense of the blood, and produces the symptoms known as cholera.

The seeds of the disease are brought in the course of travel to a locality as crystalline substance—cholera dust—or as protoplasm diffused in the moisture of the air or water, or in the fluids of the human body, in the form of cells. Under favoring conditions these elements proceed to perform each its part in nature, so that sooner or later, after finding a resting-place in a community, they develop protoplasmic fluid which, disseminated by the law of diffusion of fluids in the air and water, or resting as the dew upon articles of food, finds its way into the body. The atoms of this poison, infinite in number and pervading large areas of space, are received into the system of all as is the pernicious miasm of the marshes. The blood, acting as other fluids have been observed to conduct when impregnated with fungi, resists the changes which it is the destiny of the foreign agents to effect until the number of the invaders, or some changes in the vitality or chemistry of the impregnated fluid makes longer resistance impossible, and an explosion of the disease like a paroxysm of pernicious fever results. The ejecta from the first cases, filled as they are with cholera cells, find their way generally to a favoring soil, and develop within a few hours succeeding phases of the fungus. Thus crop after crop of cholera atoms are begotten in a prodigiously increasing progression to extend the area of infection and increase the malignancy of the disease. It may happen that the germs of cholera introduced in a locality find circumstances unfavorable for their development at the time; and although the seeds of the disease may be pretty generally sown, they lie dormant for a season.

There are certain known facts regarding the cholera which at least lend plausibility to the theory that the germ may be implanted in a district long in advance of the actual appearance of the disease. Such, certainly, is the case when the cholera "winters over," as it is said, lies inactive, it may be, through the fall, winter and spring to arise into activity the following summer.

It has long been noticed that an epidemic of cholera is often preceded for weeks by the influenza, and a marked and general tendency to diarrhoea. The reasonable assumption that both the fore-running ailments and the succeeding disease were the effects of a common cause would imply the presence of the germ of cholera in a locality long before the actual outbreak of the epidemic.

The march of the pestilence, though generally in the track of travel, is sometimes singularly abnormal as to this law. The cholera sometimes springs up in places far out of the line of apparent exposure. These variations and exceptions to the general law of portability of the disease suggest a possibility of the truth of the theory that it may be primarily sown as a temporarily inactive dust, as well as implanted as a speedily developing protoplasm. It may be, that in attempting to trace the origin of the disease by noting in any locality the first case, we err in this, that we compare the course of the epidemic with the line of travel in the presence of the attack, when possibly

it is the course of the traveler from the infected district of last year to which attention should be given. The irregularity as to the time and place of appearance may be further referred to the varying soil and temperature of the respective localities considered as developing agents of the deposited germ.

It will be noted that there have been here set forth two theories as to the mode of advance of cholera. The one, that it advances in successive crops from a first or isolated case; the other, that the seeds are sown broadcast over the countries elected for visitation, and that these are developed when and as favorable conditions arise. The number of cycles which the cholera germ may undergo in a season may vary with the locality, temperature, etc., conditions which determine the severity of the epidemic and the length of its stay in a place. Thus, at St. Louis the number of its cycles might be three-fold greater than at Bangor. And a variation in the time of the cycle, also, might influence the rate of advance of the disease.

Changes in the blood effected by the protoplasmic atoms in their act of development into cells alone produce the cholera; the presence of cells which have already completed their growth, or the material formed from them, cholera dust, does not directly induce disease. Thus, rice-water discharges abounding with comma bacillus may be drunk without injury. The subsequent deposit of these cells in the ejecta of the experimenter may, however, lead to an outbreak of the disease, of which he may prove the first victim.

One of the most singular laws of the cholera is this, that with rare exceptions it marches *onward*. It remains active in a place a number of weeks and subsides, and the places next attacked are *beyond*, relatively to the starting point, the district last devastated. In reference to the army worm this also is a fact; and in regard to the march of the insect we can plainly discern the laws, and that, whether it be held that the eggs have been all deposited by the same army of moths, or by successive broods of them. In the one case we may suppose the millers, finding the fields of favorable deposit preëmpted, pass onward to unoccupied territory. In the other, because of the devastation made by the preceding generation, the millers of the present must instinctively move onward in search of proper resting places for their eggs.

Now, as the army worm moves onward by instinctive selection, may it be possible that the cholera fungus advances by a *vis a fronte*—a species of chemico-vital affinity—a diffusion in the direction of affinities not yet exhausted. Just as the small-pox virus dwells in a community till its affinities for all are expended, and then moves onward—in the direction of the unprotected.

To the student of cholera, the parallel furnished by the army worm as to the convection of its elements, and the possibilities and proper times and methods of quarantining against them are suggestive.

Means by which man might stamp out, or keep out the myriads of army worms which sometimes in a few hours filled to the brim the cordon of ditches plowed about the grain fields, and changed in an equally short time flourishing acres of wheat into a "marble

ground," can hardly be devised. Plans by which he might unearth and devitalize chrysalides planted under every sod from Georgia to Maine are difficult to imagine. Methods by which he might successfully contend against the innumerable moths filling the air, might discover and destroy the numberless eggs deposited in every meadow on the continent are inconceivable.

How infinitely more difficult to avoid or to antagonize are the minute cells, the every way and everywhere portable dust, and the invisible, intangible, miasmatic atoms of the cholera.

And yet the farmers actually did antagonize their protean plague in all of its phases, and with a fair measure of success. They quarantined against the ever coming and ever increasing countless millions of worms. They energetically and persistently worked to keep off from the yet uninvaded fields by means of a cordon, mechanical and chemical, all possible insects—they plowed under, and deeply buried, in order to destroy, the chrysalides known to have formed; they attempted to entrap and destroy the millers by cordons of lights, and they burned the grass where the eggs were deposited.

The principles of quarantine against the cholera suggested by the theory of the disease here presented may be summed up in the following propositions:

Elements of the disease known to exist may be isolated or destroyed.

Places suitable for the development of the elements may be rendered unsuitable.

Ingesta possibly contaminated by the cholera poison may be avoided.

Badly infected districts may be evacuated.

According to this theory, during an epidemic the poison lurks in every individual. In the blood of an exposed person are two contending forces; the one the resistance of the vital fluids to the changes attempted to be made by the invading atoms; the other, the efforts of the latter to appropriate from the blood materials for their own growth.

One of the first evidences of the yielding of the forces contending for integrity of the blood is loss of the serum. The one important event in the chemical change in the blood necessary to give the victory to the ferment (invading atoms) is loss of its serum. Speaking figuratively, serum is the essential ally of the blood in its resistance to the invaders. Ejection of ever so little of this, tends to render the ejection of other portions easier, and to give the final victory to the poison.

Now, while no prophylactic measures are known, it is most fortunate for mankind that remedies are at hand which, if applied in season, may, unless the assault of the ferment be overwhelming, arrest the flow of serum and reinforce the blood in its resistance to the infection.

Even when the cholera has held full sway, when it has run its course without interference, it is not necessarily fatal. Either because the dose of the poison has been insufficient to destroy, or because in some life may continue after the virus has done its worst.

The secondary, reactionary conditions, following the collapse known as the typhoid state, are compli-

cated phenomena. They are expressions of the efforts of the system in its struggles with the resultants of the cholera paroxysm rather than a proper stage of the disease. They bear a relation to cholera which may be compared to that which surgical fever bears to injuries which caused it.

This theory of the presence of the germ of disease in the system of all involves the recognition of the principal of acclimatization in this disorder. One may become by gradual inurement habituated to the presence of the virus, and, perhaps, the majority so injured are able completely to resist it. As in the yellow fever, however, the acclimation may be speedily lost. Persons whose systems have not thus become acclimated to the poison may be, upon sudden exposure, stricken down with violence.

FOREIGN CORRESPONDENCE.

BELFAST, IRELAND, Aug. 5, 1884.

MR. EDITOR:

The fifty-second meeting of the British Medical Association was held in Belfast, Tuesday, July 29, to Friday August 1. Will you grant a little space to a delegate from the American Medical Association, that he may give an account of the proceedings to the members who did not have the privilege of attending? The meeting was largely attended, not a little attraction being added by the fact that only two of the previous meetings had been held in Ireland. Of the members sixteen were present as delegates from the American Medical Association.

Everything was done to make the meeting a success from every standpoint, and it will go on record as one of the most successful and most interesting meetings of the Society. The meeting was held in the buildings of the Queen's College, than which there could have been no more desirable place, the accommodations being ample, sufficient, and compact. The general meetings were held in the spacious halls of the library, and the sectional meetings in the various lecture-rooms—the fact that all were near and convenient being a great advantage.

Each day there were one or more general meetings at which the business of the Society was transacted.

There were besides, eight Sections, viz.: a. Medicine, b. Surgery, c. Obstetric Medicine, d. Public Medicine, e. Ophthalmic Medicine, f. Physiology and Pathology, g. Pharmacology and Therapeutics, h. Psychology. Each of which held three meetings, in which valuable and interesting papers were read and discussed.

Most admirable addresses were given by the President of the Society, James Cuming, M.D., F.R.C.S.P., Professor of Medicine in Queen's College, and Physician to the Royal Hospital, Belfast; and in Surgery by Sir William McCormac, F.R.C.S., London; in Medicine by William M. Ord, M.D., Physician and Lecturer on Medicine to St. Thomas Hospital, London; in Physiology by Peter Redfern, M.D., Professor of Anatomy and Physiology, Queen's College, Belfast; and in Obstetric Medicine by George H.

Kidd, M.D., Consulting Obstetric Surgeon, Richmond and Hardwick Hospitals, Dublin. These were all admirably written and showed exhaustive research, all with the exception of Dr. Kidd, who wrote on puerperal fever, being of a general nature, and as they will appear at length in the *British Medical Journal*, I will not take up your space with an abstract. Each and all received the most cordial attention and the best thanks of the Society were given to the writers.

In addition to the business proper of the meeting, everything was done to make the visit of the members one long to be remembered, and for this many thanks are due to Dr. Robert Esler, of Belfast, who not only was Chairman of the Excursion Committee which arranged and conducted some excursion for each day, but he wrote a special guide to the city of Belfast and the North of Ireland of 123 pages, which he presented handsomely printed and bound to each member.

The annual dinner was a very pleasant occasion.

The ladies being invited to the conversazione given by the President and Executive Committee, and to the reception given by the Mayor of Belfast, helped to make these very brilliant affairs. On Saturday, Aug. 2, the business of the meeting having been concluded, four general excursions were arranged. Each by a different route, comprised a day's trip in the North of Ireland. Of these the one to the Giant's Causeway was the favorite, about 300 members taking advantage of the occasion to visit this wonderful formation.

There were in addition, several garden parties and dinners to limited numbers, and each one who attended the meeting will long remember the hospitality extended to them.

Will also try to send you some information about the meeting of the International Medical Congress at Copenhagen.

DOMESTIC CORRESPONDENCE.

TREATMENT OF CHOLERA.

EDITOR OF THE JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION:—

It has seemed proper to me to call the attention of the profession to the valuable article on the treatment of Asiatic cholera, by Dr. S. S. Todd, in the JOURNAL for Aug. 9, not only because the subject is peculiarly opportune at the present time and the method proposed seems exceedingly rational, but for the reason that, some time ago, a similar proposition was made by a German writer, and the statement that the plan has hitherto been untried needs modification.

Prof. Samuel, of Königsberg, in 1883, published a brochure on Subcutaneous Infusion as a Method of Treatment of Cholera, in which he proposed at some length a plan similar to that recommended by Dr. Todd; the same writer has recently reiterated his views,¹ a synopsis of which I believe will be of interest and value.

¹ Die subcutane Infusion als Behandlungsmethode der Cholera, von Prof. Dr. S. Samuel, in *Berliner Klinische Wochenschrift*, 1884, No. 28.

In his opinion the essential pathology of cholera consists of a process of transudation into the intestinal canal—the original cause being the presence of certain bacilli—that, by continually robbing the blood of its watery constituents, causes it to thicken, stagnate and finally stop circulating. If the disease passes beyond the stage of premonitory diarrhœa, and the patient is already in a collapsed state it is useless to attempt any direct treatment of the transudation, as all medicaments introduced by mouth or rectum are immediately carried off, either through vomiting or diarrhœa. Even if the intestinal muscles are incapable of any exertion, as in so-called cholera sicca, the situation is not much better, for here absorption fails, a fact proved by recorded experiences.

Experience has also demonstrated that, in a majority of cases, this great loss of serum is the cause of death.

The duty of the medical attendant is therefore, in some way, to make up for this loss; and in the performance of this duty he derives some comfort, though it be scanty, from the fact that the stage of collapse is always short, lasting in survivors but from 24 to 36 hours; to whatever fact the improvement may be due, it is certain that after the expiration of that time absorption begins again and the circulation improves.

From the above reason the chief end of treatment should be the maintenance of the fluidity of the blood during this critical period. To accomplish this aim the infusion of water directly into the blood has been employed, as offering the great advantages of a direct supply, and doing away with the question of absorption. It is fair to add that all who have attempted this operation once or twice have been strongly impressed with its favorable influence. But as not one nor several injections, but an almost continuous stream is needed, we are at once confronted by the difficulty of carrying out so delicate a surgical procedure on a restless patient and the great risk of diffuse phlebitis.

The method of subcutaneous infusion is, *per se*, an innocent one, the only question that arises being whether so large amounts of water as are needed can be absorbed by the surrounding tissues, a question that experience alone can fully answer.

It is a fact that all free œdema in cholera patients quickly disappears. Beigel (*Lancet* ii, No. 13, p. 352), has already in a case that was completely collapsed made hypodermic injections of warm water in the calves, thighs, and arms, so that at first he injected in all seven ounces. Since improvement followed this measure he made two further attempts, but the patient finally succumbed.

During the epidemic of 1866, Dr. Samuel repeatedly injected substances into the calves and epigastrium. Absorption, though often slow, invariably followed.

It is probable that absorption in the subcutaneous tissue is slowest when the circulation is reduced to a minimum. But even up to the last inspiration it would take place at the spot where the circulation is longest maintained, that is, in the neck. Therefore

in bad cases the nearer to the neck the injections are made the better, and Dr. Samuel recommends that they be made in the upper part of the chest on both sides directly under the axillæ, and that they be thrown in at many different points in this region and that their absorption be aided by massage.

It is to be remembered that the lower half of the body does not absorb nearly as well as the upper half.

Trocars that are bound to irrigators and can be left *in situ* are to be preferred to needle apparatuses, in that the latter may pierce important vessels and nerves.

For injections salt solutions consisting of six grams table salt, and one gram carbonate of soda in one thousand parts distilled water heated to a blood heat are suitable.

It must always be borne in mind that in the nature of the case success can only be expected if the subcutaneous injections are followed up continuously to the termination of the stage of collapse.

The above has been written in no spirit of captious criticism, but with a full appreciation of the extreme difficulty that the busy practitioner labors under in the effort to keep *au courant* with the current literature, and is communicated with the belief that any contribution to the study of Asiatic cholera, in view of its expected visitation to our country, should be given all possible publicity.

GEO. A. STAPLES, M.D.

Dubuque, Iowa, Aug. 20, 1884.

NECROLOGY.

WOODWARD, JOSEPH JANVIER, M.D., Surgeon U. S. A., was born in Philadelphia in 1833; died of disease of the brain, near Philadelphia, 17th of August, 1884. He received his academical education at the Philadelphia Central High School, from which he received the degree of A.B. in 1850 and his A.M. in 1855, and was honored on the occasion with the position of valedictorian. After receiving his first academic degree he began the study of medicine in the office of Prof. George B. Wood, and attended lectures at the same time in the University of Pennsylvania, from which he received the degree of M.D. in 1853. His graduating thesis was on the antiseptic properties of chloride of zinc. He at once began the practice of his profession in his native city. Dr. Woodward formed a class for instruction in the use of the microscope and the study of pathological anatomy, and the examination of students preparatory to their final examination by the Faculty for their medical degree. His practice was growing, and he was becoming favorably known as a teacher and practitioner, when the war between the States broke out. He at once tendered his services to the government, and was commissioned Assistant Surgeon 5th August, 1861, and served for a time in the peninsula of Virginia. He was assigned to duty in the Surgeon-General's office 19th May, 1862, and continued in this position until his illness and death. He

was Curator of the Army Medical Museum, which grew up under his immediate supervision.

Dr. Woodward was advanced to the rank of Captain and Assistant Surgeon 28th July, 1866, and promoted to the rank of Major and Surgeon 26th June, 1876. He received commissions of brevet Captain and Lieutenant Colonel for "faithful and meritorious services during the war." To Dr. J. J. Woodward and the late Dr. Geo. A. Otis, U. S. A., was entrusted the editing of the Medical and Surgical History of the Rebellion. The medical profession of the country know and appreciate how ably this work was accomplished. His classification, naming and describing the many pathological specimens in the Army Medical Museum, was of itself a vast work, and one which will be an enduring monument to his genius, industry and accurate knowledge of the subject. It is true that in the surgical part of this he was ably seconded by his accomplished associate, Dr. Otis.

Dr. Woodward was a voluminous writer in various departments of medicine, and of the collateral sciences. A simple enumeration by title of his papers would fill several columns of this journal. His contributions were welcomed by every medical and scientific periodical, and they adorn the pages of many of them. His work was always well and conscientiously done. He had a true love for scientific investigation. His mind was analytical, and demanded evidence, which he weighed in a most searching and logical manner. He had great power of work, which he taxed severely, and to which may be ascribed as clearly as in any case I ever knew his failure of health and premature death. In 1875 his health underwent something of a strain, and for some six or eight months he suffered from a series of painful phlegmonous boils, but a little rest restored him to his usual good health.

In 1879 the doctor from overwork impaired his digestion, and for a time he suffered extremely from insomnia, but a trip to the mountains of Switzerland and rest for some six or eight months apparently restored him again to full health. The completion and character of the work done on his last volume shows no perceptible impairment of his vigor or powers. In the winter of 1880 his horse fell with him in Pennsylvania avenue and fractured his leg. This confined him to his room for some time, but he apparently fully recovered from this.

The range of studies in which Dr. Woodward was proficient and master were numerous. With the microscope he was an authority of wide and general recognition by those most competent to judge. His writings and opinions have a high value with the profession. In point of magnitude, the "Medical History of the Rebellion" is, perhaps, the most colossal professional work ever published in the United States. Upon this and his work upon Typho-Malarial Fever, and his photographic, microscopical work will probably rest his fame as a medical man and scientist. His literary work not only called for a familiarity with Latin and Greek, but with the French, German, Spanish and Italian languages, all of which he was able to read and translate with ease. His

proficiency in languages he acquired while engaged on his other work, and his last volume of the medical history of the rebellion is particularly rich in classical allusion, comparison of texts, and quotations from original authors. Dr. Woodward early identified himself with medical organizations, and was an earnest supporter of a high standard of medical education, professional worth and medical ethics. He was a member of the Philadelphia County Medical Society, and of the College of Physicians and Surgeons of Philadelphia. He was a member of the Central International Medical Congress, which met in Philadelphia in 1876, and read an able paper opening the discussion in the Section of Practical Medicine on Fever. He became a member of the American Medical Association in 1865, attended its meetings in 1866-'67-'68-'69-'70-'72-'73-'74-'75 (when he was chosen one of the Vice-Presidents) 1876-'77-'78 and '79. In 1881, at the meeting in Richmond, Va., although not present, he was chosen President of the Association. Shortly after this his health broke down and he, with his devoted wife, started on a trip to Europe in hopes of benefiting him. On the 31st of January, just before leaving, Dr. Woodward wrote a touchingly kind letter to the Association informing them of his impaired health and his purpose to travel, and the regret he felt in not being able to be present at the meeting in St. Paul. This letter was read to the meeting, and may be seen in full on the third page of the volume of Transactions for 1882.

His trip abroad, although protracted, did not stay his disease, but, on the contrary, it progressed unfavorably, and he returned home in the spring of 1883 in a worse condition than when he left. After some months' treatment in his own house he was taken to an institution in Philadelphia, which was under the charge of a personal friend and an accomplished physician, where he received every attention which friendship and the best medical skill could command, but without improvement.

Dr. Woodward was elected an honorary member of the Medical Society of the District of Columbia in 1874, and occasionally read papers before it. He was a member of the Philosophical Society of Washington, and its President in 1881. He was one of the original members of the National Academy of Sciences, and an active and valuable worker in its ranks. It was characteristic of the doctor that he always engaged in his scientific studies with zeal and enthusiasm, never saving himself labor or taking facts at second hand which he could verify by experiment or examination. He thus by his temperament and his love of true science kept himself on a strain all the time. He was a fine conversationalist and popular in society, but of late years became so engrossed in his work as to give but little of his time to mere social intercourse. He was also a good debater, possessed a fine flow of language and presented his points in logical sequence and with convincing clearness and force. Although Dr. Woodward is chiefly known outside of his near acquaintances by his writings, still he was a skillful practitioner, and one of the most accurate diagnosticians

to have been met with anywhere. His abilities in this direction alone would have assured him a large and lucrative consulting practice in Washington or any other city. Even with all his engagements and duties, both in army circles and with the city practitioners, he was always ready to advise with medical men who called upon him with a history of an obscure or embarrassing case. Scarce a medical practitioner of any note in Washington but who has repeatedly profited by his suggestions and advice in this way. The writer takes pleasure in acknowledging his many obligations to him.

July 2, 1881, he was selected, or rather detailed by the Surgeon-General, by the request of the Secretary of War as one of the staff surgeons to attend President Garfield. The labors and anxiety incident to that long and confining duty seriously impaired his health, and from which he never recovered.

It was understood that he had kept accurate notes of this case with a view to publication, but never, we believe, took it up for study or arrangement. Dr. Woodward was frequently solicited by different medical colleges to accept chairs and devote himself to teaching, but he felt as though his life-work was to complete the medical history of the war. So he worked on, and we know the result. Dr. Woodward was twice married; by his first wife he had two children, a daughter and a son. His son, Janvier Woodward, graduated with high honors at Annapolis, and is now an officer in U. S. navy. His second wife was Blanch, daughter of the late Cornelius Wendell, of this city, by whom he had three children, two sons and a daughter. The doctor's death, although expected, was sudden. His remains were brought to his late residence, 620 F street, Washington, where funeral services were held by the Rev. Alexander Kent. His body was laid to rest on the evening of the 20th, in the peaceful shades of Glenwood cemetery, in the presence of many friends.

J. M. T.

LOMAX, CONSTANTINE, M.D. Dr. Constantine Lomax was born in Guilford county, North Carolina, on the 31st day of December, 1814. On the side of his father he was of English-Irish, and of his mother, of English-Welsh descent. In both lines his ancestors were among the early colonists of this country, and both of his grandfathers were soldiers in the Revolutionary war. When about two years old, his father, Abel Lomax, and his mother, Elizabeth Lomax, with their family, emigrated to Indiana, and located in Wayne county. The state having just emerged from its territorial condition into the Union, afforded very poor facilities for education. Four short terms in a common country school were all he ever had the privilege of attending. In 1837, his father and family removed to La-Porte county, on the northern boundary of the state, and Constantine accompanied them, and continued to work upon the farm with his father until 1843, when he married Miss Rachel Van-De-Vanter, of Lagrange county. After this, he devoted himself to farming for some two or three years, when, by the influence of his brother, Dr. Wm. Lomax, he abandoned the farm and entered the office

of Dr. Daniel Meeker, of La Porte, as a student of medicine. He attended three full courses of lectures in the Indiana Medical College, and graduated on the 17th day of February, 1848. Immediately after this he located in Marion and entered upon the active duties of his chosen profession, in partnership with his brother William. In this year, with the other physicians of the county, six in all, he associated in the organization of a county medical society, of which he continued an active working member until his death. In 1850 and '51, he attended a course of lectures in the Ohio Medical College in Cincinnati, and received a diploma from this school on the 4th of March, 1851.

In 1863, Dr. Lomax was appointed by President Lincoln, Surgeon of the board of enrollment for the eleventh Congressional District of the State, a position he held until the close of the war. The partnership existing between him and his brother in the practice of medicine was, by mutual consent, dissolved in 1876. Dr. Lomax, at various times, filled all of the offices of his county society, was a member of the District and State Medical Societies, and had been a member of the American Medical Association. He was a man of marked acuteness of discernment and accuracy of opinion. While he was unassuming and diffident in discussions at the society meetings, his opinions commanded the highest respect of his fellow-members. When differing from others, which he often did, he would state the grounds of difference in such clear and accurate terms as rarely failed to convince the other members of the correctness of his views. If uncertain of diagnosis or other matters of consideration, it was his custom to so express himself without argument or other waste of words. His knowledge of anatomy was unusually thorough for a country practitioner. In canvassing the pathology of diseases brought before the society, he was noted for his aptitude for anatomical and physiological explanation of symptoms presenting themselves in the case, so that while he was the most unobtrusive of all the members of the society, there was no one whose opinions were more influential in the decisions of the meetings than his.

Dr. Lomax was naturally of a cheerful, urbane disposition. Kindness of heart, a scrupulous regard for the feelings of others, and the claims of all to respectful recognition, made him a very agreeable companion. Having an exquisite sense of professional honor, and an unmitigated contempt for the groveling charlatan, he would prefer to abandon entirely a case, rather than indulge a contest where the petty devices of a trained medical knave were to be met before the tribunal of popular ignorance and gullibility. On one occasion, he was called on to consult in the case of a lady near a neighboring country town. When he arrived, he found an Eclectic in charge of the case. He examined the lady, and was satisfied she might be benefited by a proper treatment. After going out with the Eclectic, Dr. Lomax informed him that he regarded a consultation between two antagonizing professions as being eminently improper, and very wisely forbidden by the Ethics which he was under plighted obligations to observe

and carry out, and that he could not consult with him.

They called the husband out and informed him of the fact. The husband requested the doctors to remain while he could go in and see the patient and learn her wishes in the matter. In a short time he returned and said his wife wished them both to come into the sick-room, which they did. She expressed great astonishment at learning of the prohibition of the consultation, which she could not understand, but said since it was the case, she wished both doctors to stand up before her so she could see them both at once. The doctors felt a little embarrassed and amused at the undignified requirement, but yielding to the whims of the sick woman, stood side by side before her. After a brief review, she inquired of Lomax if he understood her condition? He replied he thought he did. Then could he cure her? He thought she might be benefited by treatment. Would he give her the treatment needed should she prefer him? He said he would do the best he could. Turning to the Eclectic, she told him she felt thankful to him for his faithful attentions and efforts to relieve her, but he knew she had suffered long and was not relieved, but was steadily losing strength; that now, without any disrespect to him, she would be glad to have Dr. Lomax give her treatment. The Eclectic assured her it would be perfectly satisfactory to him. Thus, without any bad blood, the matter was amicably adjusted.

Dr. Lomax was a conscientious stickler to the Ethics, and rarely or never had any difficulty in observing them literally in the exercise of professional avocations. He was liberal and earnest in promoting all measures tending to advance the interests, honor and usefulness of the profession. In 1876, he was appointed examiner for pension applicants, and when a board was organized for the purpose, he was chosen to preside in its deliberations, a position he held until his death.

In politics, Dr. Lomax was a Republican. Some thirty years ago he united with the M. E. Church, since which he lived the life of a faithful and consistent member. His last illness was painful in the extreme. He was literally tortured to death by an incorrigible neuralgia. He died on the 6th of March, 1884, in full confidence of a blissful future.

His death made a sad and irreparable breach in a family circle of nine living children, the youngest member of which was fifty-five years of age lacking three months.

MISCELLANEOUS.

OFFICIAL NOTICE.

ANNUAL DUES from members of the Association—*Five Dollars* per annum—are payable directly to the Treasurer. Such payment entitles them to receive the JOURNAL of the Association for one year.

SUBSCRIPTIONS to the JOURNAL from those who are not members should be forwarded to the office of publication, Chicago.

BACK VOLUMES OF THE TRANSACTIONS may be procured, at reduced rates, by addressing the Treasurer.

THE INDEX to the 33 Volumes of Transactions will be forwarded, postpaid, on receipt of *One Dollar* by the Treasurer.

According to a resolution passed May 9, 1884, at the Washington meeting, continuous payment of Annual Dues is required, to retain permanent membership.

RICHARD J. DUNGLISON, M.D.,
Treasurer.

Lock Box 1274, Philadelphia, Pa.

THE WIDOW OF CLAUDE BERNARD, it would seem from an article in *Le Progrès Médical*, has come under the ban of the law through the complaints of her neighbors that she kept an infirmary for dogs and cats. The lawyer for the defense says of her that "Mme. Claude Bernard is the widow of the illustrious savant of that name, and I have heard it said that she did not make him very happy. An unique cause of dissension existed between them. Here example was not contagious. M. Claude Bernard was, as is known, the initiator, the apostle of vivisection. My client was an ardent member of the opposite party. She is persuaded—and it is she who has told me—she is persuaded that when she has saved as many dogs and as many cats as her husband has immolated, their souls will be joined in Paradise."

The establishment contained forty dogs and as many cats, it was managed by women, and extremely dirty and offensive, for which she was fined and ordered to close her infirmary.

OFFICIAL LIST OF CHANGES IN MEDICAL CORPS OF THE NAVY DURING THE WEEK ENDING AUGUST 23, 1884.

P. A. Surgeon P. M. Rixey, orders to U. S. S. "Lancaster" revoked, to continue on special duty.

Medical Director C. Martin, to be retired Aug. 21, 1884

Surgeon T. C. Heyl, detached from U. S. S. "Independence," ordered to U. S. S. "Adams."

Surgeon J. G. Ayers, detached from U. S. S. "Adams," placed on waiting orders

Assistant Surgeon L. W. Curtis, detached from U. S. S. "Adams," placed on waiting orders.

P. A. Surgeon F. B. Stephenson, detached from Navy Yard, ordered to C. S. S. "Bache."

P. A. Surgeon E. Z. Derr, detached from C. S. S. "Bache," placed on waiting orders.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM AUG. 16, 1884, TO AUG. 22, 1884.

Woodward, J. J., Major and Surgeon, died August 17, 1884.

Birmingham, H. P., First Lieutenant and Assistant Surgeon, granted one month's leave of absence. S. O. 162, Dept. of the Missouri, Aug. 12, 1884.

Wilson, Geo. F., First Lieutenant and Assistant Surgeon, relieved from duty at Fort Walla Walla, W. T., and to take station at Vancouver B'ks, W. T. S. O. 120, Dept. of the Columbia, Aug. 13, 1884.

OCCULT CAUSES OF DISEASE.

BY W. L. SCHENCK, M.D., OSAGE CITY, KANSAS.

[Read in the Section of Practice of Medicine and Materia Medica of the American Medical Association, May, 1884.]

The world moves in cycles—the earth on her own axis, around the sun, her path about the sun recording the mighty cycles of the glacial eras. Periodicity marks all nature. Theories and fashions in art and science come and go, to go and come again. “The thing that hath been it is that which shall be.” To this rule medicine forms no exception. Its theories come and go with such regularity, they are hardly worth combating. The next cycle will set them aside, but again and again they will return until we build upon absolute truth. It is useless to disturb them, except as they stand in the way of enduring progress.

The causes of disease are oft-times hidden, and we may fail to discern them, but we should avoid building upon the sand. A cause in any science is that which excites or impels—that which produces a result without which it would not obtain, and which, existing, must tend to the result. To cause is to put in operation forces capable of producing given results, and the results of a cause, except in exceptional cases, must be uniform and definite.

Let us apply this test to the causes of disease, and especially to microscopic germs as their cause. The germ theory of disease is not new. The present is only one of its many cycles. Upon my introduction to the medical world more than a quarter of a century ago, some of our professors were wont to account for the erratic movements of Asiatic cholera upon the germ theory of causation, and to-day Cohn and Pasteur are vying with each other in their efforts to demonstrate microscopic germs as the cause of cholera in Egypt, and the theory is supported by many of the most distinguished names in medicine. Bassi discovered the presence of *bottitis bassiana* in the silk-worm disease. Pasteur and Cohn measurably demonstrated the relation of microscopic fungi to fermentation, and the conclusion was quickly and generally inferred that disease was fermentation, and microscopic germs its cause, and the term septic,

from *sepein*, to rot, was applied to a most formidable class of diseases. All the world became microscopists. Polander and Davainé and Koch demonstrated the *bacillus anthracis*. Obermeyer discovered the presence of *spirillum Obermeyer*i in relapsing fever, Eberth and Freidlander the bacilli of typhoid fever, and Klebs of goitre, and Neisser of leprosy and gonorrhœa, and the search has been continued until specific micrococci have been found in septicæmia and pyæmia, in variola, vaccinia, rubeola, scarlatina, diphtheria, erysipelas, metritis, etc., etc. And why not? If specific bacilli are present in any large number of diseases, why not in all?

But when their presence has been proven and when it has been demonstrated that they are the cause of septic fermentation, of decomposition, have we proved them the cause of disease? When we consider the numbers and learning of those who affirm, it may be deemed presumption to question. But names and numbers count nothing in science. Every searcher after truth should give it as he perceives it. Only thus can truth advance.

It has been proved by all observers that the microscopic germs that are supposed to be the cause of various specific diseases, are not only present during the existence of those diseases, but are ever present in and about us. If they are the efficient cause of all or nearly all diseases, then a cycle may be made in spiritual medicine, and doctors and divines may go back to the days when all disease was attributed to the wrath of God. Erahma, the creator, is transformed into Siva, the destroyer, if he has created us and then filled earth and air with innumerable unseen foes whose function is to miserably destroy by pestilence and plague. The crowning act of creation—made a little lower than the angels, and made to be destroyed by the lowest types of animal and vegetable life! The highest creative art of Omniscience destroyed by the mad hand of Omnipotence by the meanest, lowest things that live! Of such a creation the record would hardly read “and God saw everything he had made; and behold it was very good.” We believe science will confirm the record, and truth prove a unit.

As the astronomer was struck with awe and admiration when a more powerful telescope revealed to his astonished vision other and grander universes than his own, marking incalculable years as they moved by immeasurable paths through illimitable space about some centre of incomprehensible magnitude, so the microscopist, as his instrument revealed the multitudinous creations within and around him, mak-

ing each drop of water, each breath of air, and each corpuscle of blood teem with life, confused by these innumerable and never-ending creations, wrongly inferred that the earth no longer yielded her richness to the grasses and grains, these to be consumed in animal growth and the less highly organized animal in the development of a higher type, and man himself sacrificing his life for the growth of clan and country, and the spiritual elevation of his race, but taught that omnipresent microzones, in numbers numberless, lived and moved and had their being through the destruction of the highest type of creation. They have not only been proved ever present, but capable of a most wonderful reproductive power. Cohn estimates that a single microzone can produce one hundred and fifty billions of microzones in a day, reproducing by subdivision, breaking its endoplasm into spores with inconceivable rapidity. As far as known they are the lowest, simplest forms of cells. Below them life does not exist, and everywhere they are more numerous present than all other forms of life combined. We believe it will be found their omnipresence and wonderful power of reproduction is for beneficent and not malign purposes.

It is an undoubted fact that they cause putrefactive changes in organic products, and reduce them to their elemental state, but before they can do this there must be a condition present in organic structures rendering such change possible. They are within and about us in health, and harmlessly so. They cannot produce this change in healthy living tissues, vegetable or animal. In disease they reduce to elemental conditions the products of disease, and instead of being the avenging messengers of God are his good angels, "entertained unawares." They destroy dead matter without the body and with it may enter the living tissues, not to destroy them, but to resolve into their ultimate elements the death it causes. They are the ferment that prevents the living body from becoming encumbered with dead matter, the result not only of diseased but of healthy action. Destructive metamorphosis is one of the great life principles, and every thought, every movement, voluntary or involuntary, involves tissue death.

Death is as little understood as life, but is a fixed condition, as is shown by dead tissues preserved through the action of antiseptics. Could those who believe microscopic germs the cause of disease and its destructive agency apply their germicides in sufficient strength to destroy these micro-organisms, they would turn the Creator's good into evil. Arrest the disease which causes death, but save the organic ferment that transforms the dead tissue into innocent, elemental conditions, conditions that make it serviceable in the renewal of life, that make the continuance of life possible.

If there was no other reason, the proved universality of micro-organisms forbids the belief that they are the contagia of disease. If the cause, their universal presence would involve the universal presence of disease. If, for example, micrococci variola or micrococci rubella are universally present and the efficient cause of disease, then small-pox and measles should

arise *de novo* anywhere and everywhere where unprotected persons are found.

Dr. Firera, of Brazil, reports that he found the graveyards where yellow fever patients had been buried the year before teeming with the characteristic cryptococci of the fever, and that having confined a guinea-pig in a chamber with earth taken from a grave, after five days its blood was crammed with the characteristic germ in various states of development. He considers graveyards as a perennial cause of yellow fever. Why not have the yellow fever perennially? If such observations prove anything they prove too much for the germ theory. If the causes of disease are ever present the sequents should be ever present. If the graveyard continually teems with the cause of yellow fever it should "show forth works meet for repentance." There must be some mistake about causation.

The fermentative action induced by micro-organisms is a destructive action. The putrefactive process is a process of reduction, of dissolution. The process of disease is a developmental process, a process of organization. "Every pathological product must have a physiological prototype (Virchow). Every normal cell has an inherent power of reproduction, and every physiological process is a process of normal cell production, hence every morbid cell has an inherent reproductive power and every pathological process is a process of morbid cell production. Beale says of diseased bioplasm "its particles are estimated to weigh many hundreds of times less than starch corpuscles or the scales of an insect's wing, and are capable of floating in the slightest currents of air. These diseased particles, floating readily through the air are inhaled by the lungs, taken into the stomach, absorbed by the skin, or coming into direct contact with the tissues through abraded surfaces, have, until destroyed by the fermentative action of microscopic germs, the inherent reproductive developmental power of establishing pathological processes like those which gave them birth. The cadaver, or any dead tissue, before it swarms with micrococci septicæmia, and by their agency, has undergone fermentative decomposition, is capable of producing in living tissue a typical septicæmia. After putrescence, however numerous its vibriones, it is innocent of harm. Inoculation with it will not cause septic disease.

If then the so-called disease germs are ever present, and disease does not follow their presence as sequents follow causes, and if when present in the greatest numbers they are incapable of producing disease, is it not evident there must be some devitalizing influence, some efficient cause, precedent to germ accumulation and zymosis.

In addition to the presence of microscopic organisms during disease, the germ theory is based on the fact that germicides prevent its development and arrest its progress. Many distinguished investigators have by careful experimentation demonstrated the exact strength of various agents required to destroy germ life and have found though infinitesimal themselves, their vitality is unaffected by infinitesimal dynamizations. We will only refer to the carefully

conducted experiments of Dr. Geo. M. Sternberg, U. S. A., published in the *American Journal of Medical Sciences*, April, 1883. He placed at the head of the list of germicides *mercuric bichloride*, and found the proportion in which it prevents the development of septic micrococci is one part in 40,000, and that the strength required for their destruction is one part in 20,000. He found "*carbolic acid* failed to destroy the micrococcus from pus in the proportion of 0.5 per cent.; but this amount was fatal to the septic micrococcus," when immersed in it for two hours. The average man weighs 160 pounds, and his blood 20 pounds. The dose of bi-chloride of mercury required to saturate his blood to the point of preventing the development of septic micrococci in it would be three and one-half grains, and a dose of seven grains would be required for their destruction, and the necessary dose to saturate the whole body sufficiently to prevent their development in it would be a little over 23 grains, while the dose of carbolic acid required to saturate the blood sufficiently to destroy septic micrococci would be one pound.

However true the theory that septic organisms cause and continue disease, all experiments prove that germicides, in medicinal doses, are wholly inadequate to their destruction or prevention, and hence whatever support the germ theory may have received from the action of the so-called germicides in the treatment of disease is without support, and the success arising from their use must be attributed to some other action. The amount of germicides, as well as the degree of heat and cold necessary to destroy micro-organisms will destroy the life of the patient.

A distinguished physician in an article published in the *JOURNAL AM. MED. ASSO.*, Nov. 3, 1883, says "Water containing albumenoids in solution, if allowed to become standing, is sure to undergo deleterious changes from its infection from the *ever present* atmospheric germs which utilize these products as food and reproduce in numbers utterly beyond conception. * * * The spores of certain forms of these lower orders of vegetation have a remarkable vitality, and have resisted a dry heat quite above boiling water." In a paper read before the last meeting of the American Medical Association the same gentleman places "bi-chloride of mercury preëminently at the head of the list of germicides," recommends a solution of 1 part in 2000 as the proper strength to destroy bacteric life, and says "under the light of new values preparations of mercury are likely to be restored to their old time professional confidences." In his enthusiastic advocacy of the germ theory of disease, he says, "In a purely conservative sense it is not too much to claim that it may be shown that each of these affections" (of the entire zymotic group) "has its origin from, and owes its dissemination to a *contagium vivum* of a definite particular character." * * * "In the light of recent astonishing discoveries no wise man would prognosticate a limit to our future knowledge in this direction. It is not too much to predicate as possible or even probable that the medical art in the near future will hold control over the entire class of zymotic diseases as effectually as

vaccina has controlled and relegated to an almost hypothetical danger the terrible scourge of small-pox which ravaged humanity during many centuries of the historic ages. * * The so-called germ theory has passed into the realm of demonstrated fact. The patient labors of scores of very careful investigators during the last generation have slowly elaborated the fact that fermentation is dependent upon a particular something *omnipresent in ordinary surroundings*, and clearly shown that this something belongs to one or another of the varieties of exceedingly minute vegetable organisms." "*Ever present atmospheric germs*," "*Omnipresent in ordinary surroundings*," the cause of disease and yet disease occasional, exceptional. Disease arrested through the administration of solutions of bi-chloride of mercury, carbolic acid, etc., of sufficient strength to destroy the "*remarkable vitality*" of these omnipresent germs that "*resist heat quite above boiling water*," and thus "*relegate zymotic diseases to an almost hypothetical danger*." All this "*passed into the realm of demonstrated fact*," and "*no wise man will prognosticate a limit to our knowledge in this direction*." The writer may not be a "*wise man*," but he will not only "*prognosticate a limit to our knowledge in this direction*," but will express the opinion that the general adoption of the germ theory of disease is prejudicial to progress in therapeutics and scientific medicine and is untenable both in theory and practice.

We believe the truth has been elaborated that "*fermentation is dependent upon a particular something omnipresent in ordinary surroundings*," and that that something "*belongs to one or another of the variety of exceedingly minute organisms*," but it has not been shown that disease is omnipresent, or that minute organisms are the cause of disease, or that the fermentation they produce is disease, and it has not been shown possible to follow these omnipresent organisms through the circulation, the glands, bones and tissues of the body and destroy them by any known agency without at the same time destroying the vitality of the body.

We further believe the microscopic germ, so far from being a disease germ is a beneficent agent, and the fermentation it produces, a beneficent process, and that as antiseptics cannot be used in or upon the body in sufficient strength to act as germicides without injury to healthy tissue, their benefits accrue from other causes.

If germs are not the cause and sepsis is not disease, we may be asked what is the cause, and what is disease. We may not know, but knowing what is not disease and its cause, we are relegated back to the old base, and ready to commence our search anew.

We do not know what death is, but we do know that inanimate or devitalized matter may remain unchanged or return to its original elements, but that it has no power of growth or reproduction; and whilst we do not know what life is, we know that it exists in the germ cell and in the sperm cell, which though while separated have no power of growth and only a limited lease on life, when united form an embryonic cell, capable of molecular changes, silently

evolving cells of varied structure and function, capable of cell proliferation and differentiation, each differentiated cell proliferating to a definite end. We know that in the insignificant embryonic human cell is hidden the future man. Unfolding, expanding, developing it evolves tissues and organs, through whose instrumentality a spiritual life reaches out and up to the infinite. As unseen and unsuspected beauty and perfume lie latent in the germ that grows into the full blown flower, so all the grand possibilities of life lie in the simple microscopic embryonic cell. But alas! it contains other possibilities; under this same life force morbid cells, tending to disease and death, may be differentiated.

Disease is a pathological process, but a process that has a physiological prototype. Normal cell development in its multiform phases is the physiological prototype. Morbid cell development the pathological process. The physiological process tends to perfection, to life. The pathological to destruction, to death. Each is a cell proliferation, the abnormal at the expense of the normal.

The abnormal is less tenacious of life than the normal, and may be destroyed by agencies that do not affect it. The normal may by its inherent power—the "*vis medicatrix natura*" arrest the abnormal. Strengthening this power, and arresting morbid development is the function of practical medicine, and involves other, and more, than a search after germs and germicides. It embraces the causes, condition and prevention of morbid cell proliferation and leads us to comprehend why the so-called germicides and antiseptics, of insufficient strength to destroy germs and arrest septic changes, may arrest disease and restore health. We can understand how pure air, which has no germicidal power, tends to arrest disease and why "cleanliness is next to godliness," why agents without any germicidal power or in quantities incapable of germicidal action are efficient in many septic diseases. It is true some physicians persist in attributing their action to their germicidal power, but they sin against light and knowledge. Thus Dr. T. in the *Medical News*, Dec. 3, 1883, says: "I prefer borax for routine applications in suppurative otitis media. It is more readily soluble than boracic acid, and is an energetic fungicide." Dr. Bennett reports many successful cases treated by boracic acid, while Dr. Walb says "boracic acid actually encourages the growth of germs," and Dr. Sternberg "boracic acid and sodium bi-borate are equally inefficient as germ destroyers, but both possess considerable antiseptic power." In reference to the experiments of Dr. S. we would suggest to those who adopt the germ theory, if germs are the cause of the septic process, that if they continue unaffected while it, or disease, is arrested, there must be other than germicidal or antiseptic force in the agent.

Tr. ferri chloridi is one of our most highly esteemed agents in erysipelas, typhoid fever and diphtheria, but Sternberg found it an inefficient germicide in the proportion of 4 per cent. It cannot therefore cure these diseases by virtue of its germicidal power. In diphtheria we have had very satisfactory results from a combination of sulph. quinia, sulpho-carbo-

late of soda, and sulphur in glycerine, but not, we think, because either have any considerable germicidal activity. Diphtheria is a constitutional, as well as a local disease. The tendency of its materies morbi is to lower the vitality, and yet we find mercuric bichloride, an agent of similar tendency, highly commended in its treatment, simply because it is an energetic fungicide, the germicidal power of the agent outweighing every other consideration. If it was given in germicidal doses it would be vastly more destructive than the disease. Since it has been placed at the head of the list of germicides, distinguished gentlemen exult in the thought that mercury is to be "restored to its old-time popularity." Surely the old-time experience with the drug, either by the patient or the physician, was not crowned with laurels.

Quinine is more largely and successfully used in the treatment of septic diseases than any other single agent. Yet Dr. Sternberg found it possessed a very low germicidal power. Lister had great faith in the theory that germs were the cause of disease, and saturated the air of his operating room and the wounds of his patients with carbolic acid, but, in the light of the experiments of Sternberg and others, never to a sufficient extent to destroy the germs, and with no better success than has followed his practice since he has abated his zeal in that direction.

A careful comparison of the results obtained by surgeons and obstetricians who do not use antiseptics with any intent to secure their germicidal action with those who do, goes far towards disproving the theory of germ causation. Mr. Tait and Mr. Keith, once advocates of the germ theory, have surely demonstrated that the greatest success yet attained has been reached by other means than destroying germs, and if the germicidal action of drugs can be ignored in abdominal surgery, may it not be dispensed with elsewhere? Though Volkmann and Billroth have used carbolic acid and corrosive sublimate fully and freely and have attained great success, their results have not equaled those of Tait and Keith, nor can the success they have achieved be in any measure attributed to the germicidal action of the drugs they have used, for they have not used them in sufficient strength to destroy germs.

One more thought. It is claimed specific micrococci are the cause of various diseases, because when isolated and cultivated through several generations, in a non-contagious medium, they will, if introduced into the body, produce their specific diseases. Our only reply is to quote one of the warmest advocates of the germ theory: "They are omnipresent in all ordinary surroundings." Yet without some added factor they do not produce disease.

Mycologists very generally agree that microzones are often present without the disease they are supposed to induce, that the disease is often present without the microzones, that they are frequently negative at the beginning, and most declared after the disease is fully established, when tissue disintegration is at its height, and that the pathological conditions they produce widely differ. If there is any law of causation the cause must precede the disease it pro-

duces, and when present must always tend to the given disease, be its chief factor, and produce it and no other disease. Tried by such simple tests, can bacteria, by any proof yet adduced, be considered even the occult cause of any considerable number of diseases?

A CASE OF RHINOLITHIASIS.

BY JEFFERSON BETTMAN, M.D., CHICAGO.

Read to the Chicago Medical Society.

The comparative rarity of this affection, and the interesting features connected therewith, induce me to present the following case:

Mr. M., æt. 49, consulted me June last for what he termed "chronic catarrh in the head." The trouble extending over a period of many years, he had at various intervals been under medical treatment, but the benefit he received had always been transitory in effect. Of late the annoying symptoms had become so aggravating, that he had consulted Dr. Ernst Schmidt, of this city, who kindly referred him to me. A nasal discharge, existing for many years, had of late become so copious as to necessitate a daily use of from four to six handkerchiefs. In connection with this, he was subject to periodic attacks of neuralgic headache. According to his description these attacks were hemicranic in nature, extending over the right orbital and temporal regions. As far as he had noticed, there had never been much impediment to free nasal respiration. Later examinations, however, elicited the fact that there was marked obstruction on the right side; a condition which had heretofore escaped the patient's attention.

Status præsens: Mr. M. is a gentleman of goodly dimensions, well-proportioned and to all appearance a picture of florid health. The external nose appeared congested and slightly tumefied, the borders of the nostrils somewhat excoriated. A mere superficial examination, the simple introduction of the nasal speculum occasioned violent attacks of sneezing. During the examination and subsequent operative attempts, I was very much handicapped by this exquisite hyper-sensibility of the nasal mucous membrane. Upon coming in closer proximity to the patient, an unmistakable fetor was noticeable in the expired breath. This fetor, although to a limited extent, was also imparted to the nasal secretion. The latter, viscid and slightly flocculent, filled both nostrils and necessitated a thorough removal ere permitting a survey of the parts. Upon illuminating the nares by means of reflected gas-light, a marked vascularity and thickening of the mucous membrane in general was noticeable. The tissues covering the inf. turbinated bones were so thickened, as to encroach upon and nearly obliterate the fissura respiratoria. The mucous membrane covering the septum was exceedingly congested, sensitive to the slightest touch, and in its tendency to bleed upon the slightest provoca-

tion, almost fungoid in nature. Both middle turbinated bones were sufficiently enlarged to press upon the septum. The posterior half of the right nasal fossa, as far as could be judged from a mere visual examination, seemed to be filled with an accumulation of creamy discharge. Attempts to remove it by a well-directed stream of tepid water proving futile, a cotton-wrapped probe was made use of. The nasal lumen was so narrowed and encroached upon by the hypertrophied turbinated bone and a co-existing deflection of the septum, that some difficulty was experienced in guiding and directing the probe. The parts, as already mentioned, were so sensitive that great persuasion was necessary to induce the patient to submit. Palpation soon revealed the presence of a hard, grating substance occupying the floor of the right nasal fossa. The sensation it imparted being identical with that of osseous structure, I not unnaturally was misled as regards the character of the substance. Its position, its irregular shape, all led me to infer the presence of a necrosed or carious bone. Acting upon this inference, I inquired closely to shed, if possible, any additional light upon what I accordingly considered the result of a constitutional dyscrasia. Thorough inquiry was, however, negative in strengthening the suspicions entertained. His assertions to the contrary, and in face of my inability to establish any trace of constitutional taint, I could not dissuade myself of the osseous nature of the body. Explorative examinations, owing to the sensibility of the parts, yielded but little. Seeing that under the circumstances further examinations and attempts at removal were hardly indicated, all active proceedings were temporarily checked, and the patient was advised to return in a day or two. To allay the morbid sensibility of the parts and to reduce, if possible, the acute swelling of the tissues, a detergent nasal lotion was advised to be used *ad interim*. Its use was certainly effective, as at the next meeting, two days later, there was a marked diminution of this hyper-sensibility and a considerable reduction in the volume of the tumefied mucous membrane. Under a strong illumination the exact position of the foreign body was now satisfactorily defined. Lying on the floor of the nasal fossa in its post-half, it seemed to be impacted between the bony septum and inferior turbinated bone. The exposed surface of the body was rough, uneven and unyielding to the touch of the probe. Former experience proving convincingly, that syringing would be of little or no avail in attempting to dislodge and remove it, instruments were resorted to. For this purpose I used a pair of strong aural forceps bent at right angles, the blades tipped with fine, serrated surfaces. But little difficulty was experienced in getting the body within the grasp of the forceps, however, upon traction, a firm resistance was met with. During the examination the fauces were uncontrollably irritable, defeating all attempts at posterior rhinoscopy. Anterior inspection yielded but limited information, so I apparently underestimated the size of the body. Firmly wedged in the lower meatus, it resisted all attempts to dislodge it and compelled the adoption of other means. Its immo-

bility convinced me that a removal *in toto* anteriorly would be exceedingly difficult if not even impossible. Taking into consideration the narrowed lumen of the nasal passage, such a procedure would have necessarily produced great bruising and injury of the tissues, caused annoying hæmorrhage and much suffering to the patient.

Subsequent endeavors were directed toward reducing the volume of the body and removing it piecemeal. These attempts were but partially successful, as after repeated trials but a diminutive fragment thereof could be detached. This and the objections raised by my patient, who up to this time had borne up bravely, hardly encouraged me to persist in my attempts. It was only now that the feasibility of removing it through the naso-pharyngeal space, presented itself. Fully aware of certain risks thus incurred, I was happy under the circumstances, to avail myself of any decisive measure promising relief. To effect this, I made use of a cotton-wrapped probe.

Cautioning my patient not to inspire deeply or swallow during the act, and carefully guarding the faucial orifice myself, I essayed to force the body into the naso-pharyng. space. It was the work of but a moment, and succeeded with astonishing facility. The gentleman, heeding my admonition, in another moment spat out the foreign substance. Darkish gray, almost black in color, conoidal in shape, emitting a highly disagreeable fetor,—all tended for the first moment to confirm the previous diagnosis—necrosis. It was only on closer examination, however, that the true nature of the body was revealed. Its weight, firm consistency, and the pebble-like uniformity of its unexposed surfaces were sufficient to indicate its calcareous nature. Irregular in shape, the contours of the concretion conformed to the confines of the surrounding tissues; a broad, somewhat irregular surface, corresponding to the septum, a smooth, rounded surface to the floor of the nose, and a lateral concave face which bore the impression of the inf. turb. bone. Irregular in shape, resembling somewhat a truncated cone, it is difficult to present exact data as regards its dimensions.

Its medial surface (referring to its position *in situ*) measured $1\frac{1}{2}$ centimeters in length by $1\frac{1}{4}$ centimeters in breadth, the inferior surface, smaller and rounded, $1\frac{1}{2}$ by $\frac{1}{2}$ centimeters. The medial surface was slightly furrowed and showed distinctly the impression of the serrated edges of the forceps. The exact weight of the concretion was $1\frac{1}{2}$ gram. To assure myself as regards its calcareous nature I detached a small segment with my penknife, and to my great astonishment, found embedded in its mass a large cherry-stone. The etiology of the case was now clear to me. The interest on part of my patient was naturally heightened on learning of the peculiar contents of the concretion. Incidents of early childhood were vividly impressed upon his memory, and he could in no possible manner account for the presence of the cherry-stone. Free nasal respiration was fully restored; and great relief experienced immediately after removal. To describe the case in full, it will be interesting to add that I subsequently discov-

ered a small mucous polyp high up in the same nostril under cover and almost hidden by the middle turb. bone.

Rhinolithiasis, a term first applied by Demarquay,¹ is by no means a common occurrence. Stoerk² in briefly describing it in his text-book, avers that he has seen but one example of it. It is not surprising then, that no mention is made of it in many works on general surgery. By far the greater number of cases have been observed and described by our French confrères. Both Demarquay and Poinso³ have written most comprehensive and exhaustive brochures on this subject.

In the preponderating number of cases on record, the determining cause of the concretion is the presence of a foreign body which forms a nucleus for the deposition of lime salts. Nasal concretions have, however, developed independently, and not due to the presence of any extraneous substances. In these isolated cases the inciting cause, according to Poinso³, may have been a collection of desiccated crusts or scales. The anatomical configuration of the nares no doubt exerts an important influence in the development of such concretions. Congenital or acquired atresia, stenosis of the nasal lumen, favor the retention and subsequent desiccation of nasal secretion. Graefe, according to Durham,⁴ considers a gouty diathesis a predisposing cause of rhinolithiasis. Virchow⁵ has observed and described a calcareous degeneration of the mucous membrane of the nose and accessory cells, a condition due to the so-called "Diathesis Ossifica." This state is due to an entirely different process, and must be rigidly distinguished from the subject under discussion. As already stated, the presence of a foreign body is generally the primary and inciting cause. With but few exceptions these extraneous bodies are pushed or forced into the anterior nares; an occurrence so common in childhood. It can not be doubted, however, that during an act of vomiting or retching, undigested particles of food may be forced through the naso-pharynx and lodge in the posterior nares. Barring this possibility, in the case under consideration the concretion may be presumed to have been of more than forty years development. In a similar case, lately described by Jacquemart,⁶ the trouble existed over twenty years. These concretions are, as a rule, single, but instances are not wanting in the literature on this subject (*vide* Axmann,⁷ Kern) in which multiple rhinoliths were found. In size these concretions naturally vary, from that of a lentil (Rouyer⁸) to that of a small plum (Voltolini)⁹. Both Verneuil¹⁰ and Brown¹¹ have published cases, in which the size of the rhinoliths had prevented their removal

in toto. The dimension of the concretion is to a great extent influenced by its location and confines. The favorite seat for their development is the posterior, inferior part of the nasal fossa; a situation most favorable for the lodging of a foreign body. Upon section the concentric deposition of calcareous matter can be seen in the shape of striæ or lamellæ, the foreign body or a mass of organic detritus forming the nucleus. In the case of Brown the nucleus consisted of a fatty albuminous mass, whilst Phouret¹ records an instance in which there was merely a shell of calcareous matter enclosing a quantity of fetid mucus.

Chemically they are composed principally of carbonate and phosphate of lime. The more recent examinations of Geiger and Bouchardet² also demonstrate in many cases the presence of magnesia, salts and alkaline chlorides. Rhinoliths are usually covered with a coating of soft, pultaceous, fetid material composed of epithelial debris, pus and cholesterine. The symptoms incited by the presence of these concretions are frequently not marked and are accordingly overlooked; the rhinorrhœa being regarded and treated as catarrhal. The normal amount of nasal secretion is greatly augmented and takes on a fetid character. Due to the congestion of the tissues, epistaxis is a common occurrence. The chronic vascularity induces a state of hypernutrition and cellular activity in the surrounding tissues, favoring redundancy and neoplastic changes (Billroth³); thus the not infrequent conjoint presence of polypi may be accounted for. That these polyps occasionally form an important factor, is illustrated in a case observed by Clark.⁴ It was only after the removal of a large mucous polyp, that further examination with a probe revealed the presence of a rhinolith. A noteworthy symptom and one present in many cases is the existence of a hemicrania or nervous headache. The intermittent nature of these attacks in my case is similar to an observation recorded by Verneuil. A case of Axmann's is of interest, as the hemicrania was periodically checked by the spontaneous expulsion of several small concretions. Hack⁵ has recently called attention to the reflex neuroses arising from nasal diseases, and the above-mentioned symptom may be included under the same category.

It is generally very difficult and at times almost impossible to determine the nature of the foreign body while *in situ*. In exceptional cases, situated anteriorly, its details may be discerned under a strong illumination and but little difficulty experienced in making a correct diagnosis. In the preponderating number of cases, however, the concretion lies in the posterior part of the nasal fossa embedded in the surrounding mucous membrane and covered with a mass of secretion. Posterior rhinoscopy occasionally renders valuable service in their detection. The sensation it imparts to the probe is so similar to that of bone, that this mode of diagnosis is anything but reliable. In Jacquemart's case, already alluded to, not only the

author himself but more than ten consultants had made a previous diagnosis of osteo-sarcoma. With all appliances and means of diagnosis at hand, an error is often unavoidable. In the few cases on record in which rhinoliths were expelled spontaneously, the concretions were very small and in Axmann's case, multiple. Surgical interference is as a rule necessary. Before resorting to instruments for this purpose, less energetic means should be tried. As in the removal of foreign bodies generally, a stream of water injected through the other nostril may in some cases prove effectual in dislodging the concretion. Fraenkel¹ deems the use of sternutatories worthy of trial. These means are generally inadequate and extraction per instrument is indicated. Ere any attempts are made, the parts should be carefully surveyed and the exact position of the concretion determined. Not sufficient stress can be laid upon the necessity of introducing and manipulating instruments under the guidance of the eye—in other words, under illumination of the parts. What havoc, terrible suffering and unnecessary hæmorrhage are so often attributable to the carelessness or recklessness of the operator in this regard. In general, it remains to be doubted whether any part of the body has been dealt with in so slipshod and reprehensible a manner as the nasal cavity. Even at our present day, when nasal surgery has assumed a dignified position these, to say the least, humane precautions are often ruthlessly neglected. The modern status of scientific surgery brands such proceedings as unwarrantable as they are brutal. Judging from this standpoint, even the dictum of the late Pirogoff,² who to prevent repullulation of nasal polypi advises the removal of the entire turbinated bones, must lose the weight which would otherwise be attached to it.

Various instruments have been devised for the extraction of rhinoliths. If accessible, a pair of ordinary dressing forceps, or, better still, strong aural forceps bent at right angles, will fully answer the purpose. As is frequently the case, the concretion is firmly wedged in, and must be pried out ere its removal can be accomplished. To effect this, Cohen³ advises that the point of a knife be passed under the calculus into the soft parts, and it subsequently be pried out by a blunt instrument.

Durham⁴ has devised forceps with separable blades, similar to obstetrical forceps. The size of the calculus at times prevents its removal in mass, and measures to reduce its dimensions must be adopted.

Verneuil, previous to extracting a huge rhinolith, crushed it with a sort of lithotrite. In such cases the dental drill could, no doubt, render signal service. If situated at the orifice of the posterior choana, Poinsoth advises the use of retro-nasal forceps. In post-nasal extraction strict precautions must be adopted to prevent the concretion from falling into the larynx.

ETIOLOGY OF PERICARDITIS.

BY JAMES T. WHITTAKER, M.D., OF CINCINNATI.

[Read in the Section of Practice of Medicine and Materia Medica of the American Medical Association. May, 1884.]

Pericarditis is a disease of greater frequency than is generally believed. The statement made by the author of this paper in the Cincinnati Academy of Medicine that pericarditis is ordinarily oftener overlooked than recognized, having been denied by several members, was strikingly confirmed by an ex-interne of one of our largest hospitals, who observed that of the five cases which had occurred in his service, the diagnosis was made in *intra vitam* in no single case. The existence of the disease in every case was made apparent only on the post-mortem table. Maurice Letulle, *Gaz. Med. de Paris*, 22-50, 1879-80, remarks that of all acute or chronic diseases, pericarditis oftenest runs a latent course.

The failure to recognize pericarditis depends upon the fact that so few of the symptoms of the disease are local. It is only in the face of effusion, and mostly of some magnitude, that signs pertaining to the heart are manifest.

Then if we sum up all the possible causes of pericarditis we observe that in most cases the disease is independent of rheumatism. Rheumatism remains of course the most frequent of any one cause of pericarditis, largely because of the frequency of rheumatism. Rheumatism is the most frequent of a great group of diseases produced by micro-organisms. Any disease produced by micro-organisms may be attended by pericarditis.

Medical teachers and clinicians so often emphasize the fact that pericarditis is a sequel to rheumatism that in the absence of rheumatism the existence of pericarditis is not even suspected. The failure to recognize pericarditis depends largely upon the fact that the existence of the disease is not suspected. For when the suspicions of the practitioner are aroused the diagnosis is generally easy. A striking illustration of this fact I saw in a case that occurred in my practice a few months ago. The patient had been the victim of unsuspected pericarditis, with effusion, for fifteen years, at least the same symptoms had been present in greater or less degree all that time. The prominent symptoms were pallor, dyspnoea, such vertigo as to compel the recumbent position, occasional cough and a pulse so feeble as to fade away when the arm was held at right angles to the body.

Digitalis and alcohol administered from time to time obviated imminent collapse. There was undoubted increase of dullness over the region of the heart which had been taken for dilatation. By aspiration one pound of serum, at first clear, later brownish and flocculent, was withdrawn from the pericardium. The symptoms of immediate danger soon disappeared. But the long pressure and maceration had weakened the walls of the heart to such an extent as to prevent perfect recovery. This was my third case of long continued unsuspected pericarditis with effusion. In

every instance inquiry had been made as to the previous existence of rheumatism, and in the absence of it no further attention had been given to the heart. It is not safe to exclude pericarditis in the absence of preëxistent rheumatism, first because pericarditis arises in consequence of so many other conditions, and second because the pericardium may be in rheumatism the first and only joint (so-called) affected.

The frequency of occurrence of pericarditis is best shown by statistics from hospital practice where accurate records are kept and full autopsies are held in all fatal cases. The latest statistics in easy reach are from the general hospital in Vienna. According to the report for 1880, there were treated during the year 23,249 cases of disease of all kinds. Of this number 551, about one-fortieth of the whole number, were cases of rheumatism. However, but 390, about one-sixtieth, were cases of rheumatism of the joints. Pericarditis occurred 32 times, or once in every 726 cases of disease of all kinds. The point of especial interest is the fact that the pericarditis was a sequel or consequence of rheumatism in but six cases, while in 26 cases, that is five times as often, the disease depended upon other causes. Endocarditis, it may be mentioned in passing, occurred but 15 times. Pericarditis was therefore in that year twice as frequent as endocarditis. This ratio may have been an accident, or it may be that endocarditis only seems more frequent, because it leaves valvular lesions. Patients recover or die of pericarditis quickly, as a rule. Cases do not accumulate as in endocarditis.

The older statistics based simply upon clinical observation speak for the greater frequency of endocarditis. Thus Sibson's record shows three times as many cases of endocarditis. But clinical observations can give no precise information regarding the frequency of pericarditis for the very reason that the disease, so often latent, is overlooked.

Exact information in this respect can come only from the dead room. Duchek claims to have found evidences of pericarditis 89 times in 590 post-mortem examinations, that is in a fraction over 15 per cent. of all the autopsies made, and while this ratio must be regarded as an overestimate, for the reason that Duchek included in his diagnosis the cases of so-called milk spots, which are now no longer regarded as pericarditis in the true sense of the term, yet making allowance for the tendinous spots which are especially frequent in ages when true pericarditis is especially infrequent, it is seen that pericarditis is a comparatively frequent disease. Perhaps the statement of Willigk that pericarditis is encountered in 4 per cent. of autopsies is nearer the truth in that this statement is based upon observations made during the earlier periods of life. The relative frequency of pericarditis is dwelt upon, for the reasons, first, that it makes a great difference in prognosis and treatment whether the outside or inside of the heart is affected, and second, because we diagnosticate diseases in the order of frequency. Later observations only serve to confirm the statement of Bauer to the effect that "formerly and up to the close of the last century, pericarditis was considered a rare disease; since then,

it has been proved to be of quite frequent occurrence."

It is universally conceded that pericarditis occurs oftener among males than females. Of the 32 cases cited from the Vienna hospital, 23 were males. Louis says of his 106 cases that only one-fourth were females, a ratio which agrees with the observations of Hache. Bamberger's ratio was 38 males, 25 females. Sibson, who saw the largest proportion of females of any author, observed, nevertheless, the preponderance of males; of his 63 cases 35 were males, 28 females. This ratio points to the greater liability of males to the diseases which cause pericarditis.

Excluding the cases of so-called tendinous spots, which are now regarded as simple friction scleroses or hyperplasiæ of senescence, it is as generally admitted that pericarditis is a disease of youth and maturity. Grisolle and Bamberger unite in the statement that the maximum frequency of the disease occurs between the ages of 20 and 30. The appearance of the disease at any period of advanced life is, of course, not excluded by this statement, and emphasis should be put upon the fact that undoubted cases of pericarditis have been observed in foetal life; yet the period of occurrence of maximum frequency points unmistakably to the class of diseases most responsible for pericarditis, viz.: the acute infectious diseases.

Just here it may be mentioned that pericarditis occurs in all lands and climes. Hirsch quotes from Morehead the remark "Complicating pericarditis or endocarditis is, I believe, as common in one country as another. Epidemics of pericarditis are cited by Friedreich from Trécomb (1755) in the siege of Rocroy; by Hubert (1814) in the siege of a garrisoned fort, in connection, Friedreich thinks, with pleuropneumonia; and by Lalor in connection with an epidemic of febris continua in Kilkenny in 1848-49. The epidemics of hæmorrhagic pericarditis observed by Seidlitz, Kyber, Himmelstein and others, along the Russian coast, and among the marines, at Moscow, Sebastopol, etc., clearly arose from scurvy.

The relation of occupation to pericarditis has been best shown by Sibson, who observes that "servants formed fully two-thirds of the whole of the female patients affected with pericarditis." Girls engaged in the hard labor of a servant at work, at a tender age, from morning to night, when attacked with rheumatism, to which they are so subject, are all but certain to have inflammation of the heart without or within. They are growing, he says, their frame is not yet knit, they are sensitive to cold and wet, and they are subject to palpitation. It is interesting to note of Sibson's cases that pericarditis occurred in none of his females of sedentary occupation, needlewomen, etc. The influence of hard work is still further proven in the analysis of his male cases. "*Ubi stimulus ibi affluxus.*"

Pericarditis is described in the books as being primary and secondary in its nature, and much confusion exists as to what is meant by primary pericarditis. If by primary is meant a spontaneous or autochthonous inflammation, the term should be discarded altogether, for it may be said that pericarditis never

arises in this way. Pericarditis is, strictly speaking, always a secondary or deuteropathic malady. There are met, it is true, occasional cases where the cause has not been or cannot be discovered, and these cases might better be labelled inexplicable than primary. All modern writers agree as to the great rarity of so-called primary pericarditis. Duchek saw only one case in 89, Bamberger but 4 in 63. Friedreich with his wide experience, met but two cases in which he could discover no cause for the disease. Since the field of catching cold is being daily more and more contracted in the etiology of disease, it is wiser to be agnostic regarding inexplicable cases than to appeal to doctrines incapable of demonstration and hence bound to become obsolete.

An etiological division of cases more in accord with existing knowledge would be into consecutive (or mechanical) and infectious (or mycotic). Under the head of consecutive origin would fall the cases of insult or injury to the pericardium from without, as by traumatism, by perforation from a gastric ulcer, from the œsophagus, from an abscess of the spleen, from pulmonary and pleuritic processes, echinococci, aneurisms, caries of the vertabræ, sternum and ribs, mediastinal affections, inflammations of the mammae, skin diseases—in short, all involvements of the pericardium by contiguity or continuity of structure, including under this head also extensions of inflammation from the heart itself.

While these cases of so-called mechanical origin form a respectable contingent of all the cases, they nevertheless remain in the minority, all combined, when compared with the inflammations or processes secondary to the infectious diseases. As these mechanical causes of the disease are for the most part apparent, or may be discovered by careful search, and as the pericarditis in these cases is only an accident, so to speak, in the history of the original malady, they may be properly relegated to chapters on the possible complications of the various maladies.

Pericarditis proper belongs as a link in the chain of the acute infections. Probably the time is not far distant when separate forms of the disease will be recognized as dependent upon different etiological factors. Just as we now recognize as very different affections, the inflammation of the lungs produced by a trauma, by an embolus, an abscess, a catarrhal process, etc., from a true croupous pneumonia, we may come to consider as a separate affection the pericarditis which develops in the course of the infections in consequence of the immigration into its structure of micro-organisms.

There are special reasons why these micro-organisms come to be deposited by preference in the serous membranes and by especial preference in the pericardium. In the first place, the circulation in these structures is very sluggish, is stagnant at times, and just as uric acid in gout comes to be deposited guttatum in the big-toe joint, over the knuckles, in the lobule of the ear, etc., places where the circulation of the blood is slowest, border lines of the circulation, as it were, so micro-organisms come to be colonized in the serous membranes. In the second place, the lymph vessels are so exceedingly abundant in all serous membranes

as to make of them veritable lymph sacs, whose delicate canalicular walls offer no obstacle to the rapid egress of migratory blood corpuscles, to say nothing of the infinitely more minute, and in some cases, more actively moving micro-organisms.

Whatever the explanation, the fact remains as long ago observed that all the infectious diseases are liable to be complicated by pericarditis. In former times it was the habit to refer this complication to differences in the chemical admixture of the blood, or to ferments in the blood. In our day the affections of the serous membranes are explained by the presence of schyzomycetes.

It is well known that the pericardium is not alike affected by all infections. Certain forms of them show distinct predilection for this structure, and so notoriously is this true of acute polyarticular arthritis, that it is, as has been stated, the habit of many practitioners to exclude pericarditis in its absence. It is undoubtedly true that acute joint rheumatism remains the most prominent factor in the etiology of pericarditis, that it causes, or better, is attended with more cases than any other one factor; Bamberger claims that 30 per cent., Chambers and Thompson 16 and 20 per cent. of cases arise from rheumatism; but it is equally true that there is no other acute infection which may not be followed by pericarditis.

If pericarditis is to occur in rheumatism, it shows itself by preference between the fourth and fourteenth days of the disease. While it is always a possibility in mild, brief or protracted cases, the rheumatisms marked by severity or fugacity are rather more liable to entail pericarditis. But it is the youth of the patient that is of all the most inviting or predisposing element. The young of all animals show much greater susceptibility than the old to ail the mycoses.

It is not the intention to underestimate the role of rheumatism in the production of pericarditis, but to show cause for it, and more especially to emphasize the fact that almost any of the acute infections may act in the same way.

Next in frequency to acute joint rheumatism in the pathogeny of pericarditis comes pleurisy. Morgagni and Corvisart remarked this complication in their day. Duchek claims to have seen in 43 cases of fresh pericarditis an associate pleurisy 22 times; but inasmuch as the freshness or age of the pleurisy is not remarked, it is fair to infer that the order of sequence, in some of the cases at least, may have been reversed. In Bamberger's cases of pericarditis, 10.5 per cent. arose from pleurisy and pneumonia.

Tuberculosis affects the pericardium in both ways. That is the process may by contiguity inflame or a vomica open up the pericardium to produce the disease in a mechanical way. Or the micro-organisms of tuberculosis may lodge and multiply upon the serous surface, just as upon the cerebral meninges or tunica vaginalis, as conveyed thither in the lymph and blood supply. Bamberger's statistics show pericarditis in 14 per cent. of cases of pulmonary phthisis, but it is impossible to eliminate the role of pleurisy in any of these cases.

I can find no statistics declaring the relative fre-

quency of pericarditis in the various acute infections; although it is stated in the history of nearly all of them that this complication does occur.

In pyæmia and septicæmia as typically represented in traumata and puerperal fever (so-called), pericarditis with its frequent associate endocarditis is the complication which directly or indirectly is the most frequent immediate cause of death. It occurs in all three forms of typhus, the exanthematic, recurrent, but most rarely in the abdominal form. Measles, scarlet fever and small-pox are attended with pericarditis occasionally only in the less severe, as a rule in the malignant form of these diseases. It is not very rare in cholera, and is quite common in epidemic dysentery along with or independent of the rheumatism which sometimes follows dysentery. In erysipelas, diphtheria, cerebro-spinal meningitis, pericarditis not infrequently constitutes the last link of the disease process. These are all diseases in which there is already either positive or strong presumptive evidence of mycotic origin.

But pericarditis may ensue upon even the lightest infections. Perhaps one of the most interesting statements that could be made in illustration of this fact is that of Bednar, who several times observed pericarditis supervene after vaccination. In one case an acute dermatitis developed in 24 hours after vaccination with a simultaneous pericarditis. In a second case, a sharp diarrhoea, subcutaneous abscesses and pericarditis proved the order of sequence. In a third case the pericarditis developed on the thirteenth day after vaccination without intervening disease.

In Bednar's 36 cases of pericarditis the disease was found independent of other demonstrable lesions only four times. Thirty of these cases occurred within the first month of life, four in the second, and one in the third and fourth months. In all cases the disease was attributable to puerperal processes in the mother which, in the author's words, "extended their injurious effects to the child, and in consequence of acute decomposition of the blood developed fibrinous or purulent exudations in various organs, and frequently in the pericardium. The disease proved fatal, as a rule, within the first 16 days of life."

Since the investigations of Klebs and Koester have shown of endocarditis that the mild, so-called acute or later verrucose forms, as well as the malignant or ulcerative forms, are of mycotic origin; that the difference is in degree, not in kind, and that micro-organisms can be demonstrated even though no source of immigration can be discovered, the nature of endocarditis seems well understood.

Endocarditis and pericarditis are very frequently found associate. The older clinicians speak of endo-pericarditis just as they speak of pleuro-pneumonia. It is therefore safe to infer, so far as it is safe to infer anything, that pericarditis, independent of the consecutive cases, is part of a general mycosis. The prophylaxis and treatment of the disease based upon what is known of its etiology, that is the rational or scientific treatment, calls for the antimycotics, cold and rest.

THE INFLUENCE OF CLIMATE ON THE TREATMENT OF CHRONIC CATARRH OF THE MIDDLE EAR.

BY JOHN F. FULTON, M.D., PH.D., PROFESSOR OF
OPHTHALMOLOGY AND OTOTOLOGY OF THE MIN-
NEAPOLIS MEDICAL COLLEGE.

[Read in Section of Ophthalmology, Otology and Laryngology of the American Medical Association, May 7, 1884.]

ST. PAUL, MINN.

While I cannot, from the nature of the subject, give anything in this paper that is new to the experienced aurist, I hope to elicit a discussion and by so doing obtain the views held by American aurists upon a subject of immense importance. A little more than three years ago, in a private conversation with Dr. Francis Atwood, he made the remark that cases of chronic catarrh of the middle ear improved rapidly under the influence of the Minnesota climate.

Dr. Atwood had a large practice and wide experience in treating this class of cases, extending over nine years of active work. He also had the opportunity to study the contrast in the results of treatment in a climate like that of Boston and that of Minnesota, and was deeply impressed with the far more encouraging results obtained in the latter climate.

Since that time I have been investigating the subject, and propose to give the results of the investigation in this paper.

In looking up the literature of the subject I find that but little has been written in regard to climate as a remedial agent in the treatment of this most distressing and obstinate disease. This is all the more surprising when we take into consideration the fact that nearly all the remedies known to therapeutics have been resorted to and have failed lamentably in the treatment of chronic otitis media. One remedy after another has been tried, only to be abandoned after having been tested by the great regulator—clinical experience. The importance of climate in the treatment of diseases of a similar nature in other organs on the one hand, and the very serious nature of the disease of which we speak on the other, will suggest at once the great practical interest of our subject.

For chronic non-suppurative diseases of the middle ear do not only constitute about one-half of the cases that we are called upon to treat in private practice (Roosa), but give rise to some of the most annoying symptoms that we are ever asked to relieve; which in their worst form are a constant source of terrible annoyance, leading the unfortunate victims sometimes to seek relief by suicide or by ending their days in an insane asylum. A disease which if neglected or maltreated and allowed to progress becomes as incurable as glaucoma absolutum or atrophy of the optic nerve.

These considerations impress upon us the impor-

ance of resorting to every possible means of getting control of the malady at the earliest possible stage, and putting the patient under the most favorable surroundings to obtain relief. However widely otologists may disagree as to certain factors in the treatment of chronic otitis media, there is a perfect unanimity of opinion among them that the most important part of the local treatment is stimulation, not only of the mucous membrane of the tympanum, but that of the Eustachian tube and posterior nares.

Even the most conservative make use of mild stimulants, such as hot steam, vapor of iodine, ether or chloroform. Although they may not agree with the more heroic, who resort to vapors of turpentine, sal ammoniac and acetic acid, or the still more heroic, who make use of inter-tympanic injections of solution caustic potash, caustic soda, chloral hydrate and the various astringents. Although most of these have been discarded by the intelligent aurist of the present day, yet the rational of the treatment remains the same, viz.: To stimulate the parts, tone up the relaxed tissues and blood-vessels, and encourage absorption of the exudative or inflammatory products. My own experience would indicate that these processes of repair receive valuable assistance in a cold and stimulating atmosphere in which there is a minimum amount of moisture.

Every otologist must have felt that after the membrani tympani has been forced into its proper position, and the hyperæmia of the drum cavity disposed of, the bands of adhesion broken up, or if possible divided, after the rigid and sclerosed condition of the parts has received the best possible attention, and the Eustachian tube has been made pervious to air, still there remains something to be done.

This is best accomplished, I think, by placing the patients under the most favorable climatic influence, it being the most powerful agency for the relief of this condition.

Dr. Pomeroy, in his most excellent and practical work (*Diseases of the Ear*), says: "A change of climate often relieves a hyperæmic condition of the tympanum in a few hours or days."

Politzer, probably the greatest living authority on diseases of the ear, says: "Change of air and residence in a mountainous country have a very favorable influence upon the course of chronic otitis media."

"In patients in whom the local treatment continued for months remained without results, I have observed pretty often a complete cure when they left the town and lived for several months in a mountainous region."

Certainly no higher authority could be referred to, nor stronger statement made, in regard to the efficacy of the climatic treatment of chronic otitis media. There is a wide difference of opinion among general practitioners as to which is the more favorable for phthisical patients—cold or warm climate. But the best authorities seem to agree, that prior to the stage of breaking down of tissue and the formation of cavities, such cases do better in a cold climate. And just so it is with the middle ear catarrhs. The non-suppurative forms of the trouble improve, but the suppurative cases do badly.

I have many cases on my note-book to show that patients suffering with chronic otitis media improve rapidly under the influence of our Minnesota and Dakota climate, but that cases of chronic suppuration become rapidly worse or extremely obstinate, but improve when sent to a milder and warmer climate.

When we are reminded that little or no dependence can be put in therapeutic agencies, and that all forms of treatment are highly unsatisfactory, and that the experience of the best aurists has proven that much good can be accomplished by a change of situation, it seems strange that it has not been more extensively resorted to. Perhaps one reason is the slow and tedious nature of the disease, it being difficult to get the patients to realize that it is necessary for them to make a business of getting well.

But what climate shall we select for these patients? If made hap-hazard without regard to the wants of the individual cases, more harm than good is likely to result.

This introduces the subject of humidity, altitude, temperature, ozone, duration and velocity of the winds and the country over which they blow, elevation above the level of the sea, sea voyages, atmospheric pressure, etc.

These are subjects which can only be hinted at here as they have not yet been studied in regard to their effect on aural troubles.

In order to show the assistance which our own climate gives in the treatment of chronic catarrh of the tympanum, I wish to analyze one hundred cases that I have treated, fifty of which were treated in St. Paul and fifty in Altoona, Pa. The average duration of the disease in the Altoona cases, four years; but of the St. Paul cases, five years.

The treatment was the same in both places, its average time in all cases here reported was three months.

In Altoona the number of cases cured were four; improved nine; and unimproved twenty-seven.

Of the St. Paul cases, eighteen were cured; twenty improved, and twelve unimproved.

What I mean by cured, is that the acuteness of hearing comes up nearly to a normal standard, and the subjective symptoms have disappeared. So the results obtained were vastly superior in Minnesota, and so far as I have been able to ascertain this has been the same experience as other otologists who have had the opportunity to study the effect of this most excellent climate on chronic otitis media. The season of the year in which these cases do best is from the first of Sept. to the latter part of Nov., during which time there are not so many sudden changes, and there is a combination of atmospheric conditions which render the climate as pleasant and exhilarating and bracing as can be found on the globe.

The most perfect sunshine, lasting for days and months during a favorable season gives rise to a sensation of stimulation that is the delight and astonishment of every new comer.

A number of cases have come under my observation, who have been vastly improved by the climate alone. One of the chief factors in bringing about these good results is the dryness of our atmosphere.

It is a fact which needs no demonstration that the amount of humidity of any locality depends largely on the source of its winds, they being the great water distributors of the earth.

Minnesota is so situated that the winds that reach her are robbed of the greater part of their moisture; this is the case both in winter and summer. The prevailing winds of fall and winter are the returning trades from the Pacific Ocean which have lost their moisture on the different mountain ranges of the far west, having come to us over half the continent (Staples.) It is well to notice also in this connection the difference between the north and east winds of Minnesota and those of the Eastern States.

To the latter States these winds blow over the region of the Great Lakes, Hudson's Bay and the Atlantic Ocean; but these winds blow over a vast area of territory as large as all of the United States east of the Mississippi River before they reach Minnesota. And so with the southern winds of summer, while they have sufficient humidity to be essential to life and vegetation, they are not over-charged with moisture like the Eastern and Southern States. The absolute humidity per cubic foot at St. Paul is 0.92 grains; at Jacksonville, Fla., it is 3.81 grains, and at San Antonio, Texas, it is 3.51 grains; thus the humidity is three times greater in Florida.

Another source of benefit is the invigorating influence of the bracing tonic atmosphere that rapidly builds up the general health.

Dr. Jones, of St. Paul, who has made a faithful investigation and a special study of our climate, says: "There is an increased demand for food, and an increased ability to digest it.

"The power of assimilation being strengthened, there results as a natural consequence, an evolution of muscular, nervous and glandular force."

It can be easily understood how this, both directly and indirectly, exercises a most favorable influence upon the pathological condition of the middle ear caused by the chronic catarrh process, by stimulating the parts locally and by toning up the general health, assists in the absorption of the inflammatory products, and in restoring the delicate mucous membrane to a healthy condition.

The following case illustrates well the powerful assistance given by climate in the treatment of chronic aural catarrh.

The patient first came under my care in Altoona, Pa. He was twenty-four years of age and had been annoyed by the disease for five years.

He complained of constant tinnitus, a feeling of fulness in both ears and at times pains would radiate in different directions from the ears. At regular intervals he was much annoyed by vertigo and was extremely anxious to be relieved. He was also a victim of nasal catarrh of a severe type, the mucous membrane of his nose being very irritable; when out driving it would swell up so as to completely obstruct nasal respiration. He had considerable trouble in following rapid conversation.

Both ear drums had lost their transparency, and presented the usual appearance so characteristic of chronic catarrh of the middle ear. They were some-

what sunken, and the handle and short process of the malleus quite prominent.

He could hear the watch only on contact; but bone conduction as tested by the tuning fork was good. This case was under treatment for about six months in Pennsylvania, with only negative results. At times it seemed as though some of the symptoms were relieved, only to return with increased severity.

Now this same case came under treatment again in St. Paul, and was submitted to the same treatment, but with far different result. The patient acknowledged marked improvement within a few days. He lost his sensation of fulness and ceased to be annoyed by the pain, and the attacks of vertigo were altogether removed.

That which was still more satisfactory, was the marked improvement in the acuteness of hearing, as attested by the watch and the voice.

This case shows to a remarkable degree what can be accomplished by a change of situation and the influence of a stimulating atmosphere in the treatment of this most obstinate and extremely annoying disease.

I have a number of other cases on my note-book who have been treated in other climates without receiving benefit, but who improved rapidly under the stimulating influence of the Minnesota climate. The best results, however, were obtained with those cases that had come recently from other countries, the cases which originated in our climate being the most obstinate. Another agency that may have some influence in bringing about these favorable issues is the electrical potential.

Unfortunately, no instruments have yet been devised to accurately record the relationship of this element to certain localities.

MEDICAL PROGRESS.

MATERIA MEDICA AND THERAPEUTICS.

IODIDE OF POTASSIUM IN PNEUMONIA.—Dr. Luigi Gualdi, of Rome (*Lancet*) considers (with Schwarz) pneumonia not as a local disease with general symptoms, but as a general disease with local effects. He gives the iodide of potassium in forty-centigramme doses every two hours, at the same time applying the ice-bag over the seat of pulmonary inflammation. In thirty-nine cases in which he practiced this treatment he had excellent results. In all, without distinction, he observed that the sputum, from being viscid and tenacious, became, before the second day, fluid, resembling bloody serum; that with the cessation of the fever the exhaustion also ceased, although the physical state of the lung was not improved—nay, in some cases aggravated; and, finally, that in all the convalescents the appetite was so sharpened that the ordinary diet had to be considerably increased. The mortality was 6 per cent., while of the two who died one could not be included in the calculation, because, being affected with pneumonia of the apex with furious delirium, he took only two grammes of the iodide of potassium. It is worth remarking, contin-

ues Dr. Gualdi, that the fever and the exhaustion ceased, although the physical condition of the lung remained unchanged, thereby confirming Schwarz's position that the fever is independent of local alterations; also Jürgensen's contention that the cause of the exhaustion resides not in the change in the lung, but in the fever, seems to be similarly confirmed. Dr. Gualdi concludes that from his experience the treatment by the iodide succeeds better with the youth of either sex than with adults; that the iodide should be exhibited at the beginning of the disease, to insure an immediate and perfect result; that the iodide is efficacious over the fever and the exhaustion, but not over the localization, which latter indeed may even be extended under the treatment; that the iodine and potassium combined separate in the organism, so that each has its special virtue; and, finally, that the action of the ice is secondary, inasmuch as it operates on the effects, and not on the cause of the disease. It is useful in the congestive stage, hurtful when the contents of the air-cells are already solidified and the lung indurated.

ACTION OF CERTAIN MEDICINES ON THE CEREBRAL CIRCULATION.—Curci (*lo Sperimentale, Italia Medica, Jour. de Med.*) employs an experimental method, based on the estimation of the increase or diminution of the cerebral mass, as influenced by the amount of blood flowing through its vessels; if a certain medicine produces an augmentation, it is considered as producing hyperæmia, and the contrary if a diminution.

The cranium of the animal being trephined and the brain exposed, a canula of the same diameter, and open at the two extremities, is introduced into the perforation. The free extremity is connected with a tube, which is in turn connected with a manometer of water. The whole of the apparatus must be hermetically closed and filled with fluid—the manometer with colored water, the rest, and especially the canula, with oil. The advantage of the oil is that while it bathes directly the surface of the brain, it is not absorbed, and consequently does not diminish in quantity, which eliminates a chance for error. The manometer tube is only 3 millimetres, which renders the changes in its level the more appreciable.

It is necessary to bear in mind the fact that the efforts of the animal will of themselves influence the level of the fluid, and by patience wait until the animal becomes calm before beginning the experiments, as calmatives cannot be given.

Chloroform and ether produce a relative anæmia of the brain.

Hydrate of chloral was found to produce weaker cerebral pulsations than normal, the author considering that the blood pressure in the longitudinal sinus descended considerably under its influence. Consequently, if the diminution of the cerebral mass on the one hand, and the lowering of venous tension on the other, be considered, it follows that the blood flow diminishes, and that there is a certain degree of cerebral anæmia.

Paraldehyde. This new drug gave results identical with those of chloral, viz., diminution of the cere-

bral mass, from which was deduced a diminution in the flow of blood to the brain, and consequently relative anæmia.

Therefore, chloral and paraldehyde are indicated as hypnotics in all cases where there is hyperæmia or inflammation of the brain, but their use is not justified in degeneration, atrophy, etc.

Nitrite of amyl produced a considerable increase in the cerebral pulsations, and its use in syncope and cerebral anæmia is, consequently, justifiable.

Morphine produced an augmentation of cerebral volume and vascular tension, and is, consequently, a hyperæmiant.

Atropine produced such contradictory results as to render any positive conclusion difficult, but in a large dose a constriction of the vessels was observed, and the brain became pale and diminished in size, so that the drug was considered as an anæmiant of the brain.

Quinine had more of a tendency to produce anæmia than hyperæmia of the brain. It counteracts the hyperæmic action of morphine. Therefore, quinine is not contra-indicated in those diseases liable to cerebral hyperæmia, but its use, on the contrary, is justifiable. Quinine has been found useful in insolation, probably from its tendency to counteract hyperæmia.

MEDICINE.

ON A LITTLE KNOWN SYMPTOM OF SCIATICA.—Beurmann (*Archives de Physiologie Normale et Pathologique*) draws attention to a sign which is not noticed in the classical description of sciatica, which is readily recognized by the bed-side of the patient, and which is sometimes of very considerable diagnostic value.

The patient is made to lie in his bed on his back, and is told to allow the affected leg to lie perfectly passive. If now, with the leg fully extended, the physician flexes it at the hip, the patient at once experiences acute pain, darting down the course of the nerve from the buttock downwards, and which is most severely felt in the neighborhood of the great trochanter. If, however, the leg be first flexed upon the thigh before the thigh is flexed upon the abdomen, it will be found that no such pain results from the movement.

It would seem that this pain is due to tension of the sciatic nerve, which, with the first of these movements, is considerable, but which does not take place with the second.

That this hypothesis is correct, Beurmann abundantly proves by various experiments which he conducted on the dead subject.

This sign of sciatica appears to possess very considerable diagnostic value, and will probably suffice at once to distinguish sciatica from several conditions, which may simulate it, such as crural neuralgia, hip-joint disease, etc.—*Edinburgh Clinical Journal*.

ON PEPTONURIA.—M. Ch. E. Noury has written a thesis on this subject, the review of which in the

Annales des Maladies des Organes Genito-Urinaires, in which he gives 1, the history of the subject; 2, a description of the principal methods used for determining the presence of peptones in the urine; 3, an examination of the pathological conditions coexisting with peptonuria; and 4, the pathogenic interpretation of this symptom and its clinical importance. He arrives at the following conclusions:

1. The peptone is found in the urine of certain patients. Among the methods used to determine its presence, those given by Hofmeister are the only reliable ones. (Precipitation by alcohol, tannic acid, and phosphotungstic acid).

2. Peptonuria is found in two distinct groups of diseases: one local (pleurisy, chronic catarrh of the bronchi), the other general (scorbutis, phosphorus poisoning, etc.)

3. In the local affections, peptonuria is associated with the resorption of an exudation rich in cellular elements.

4. In these cases, the conditions which influence the appearance, the progress, the abundance and the duration of peptonuria are connected on the one hand with the exudation itself (its abundance, richness in globules, disorganization and the more or less rapid reabsorption of these same globules), and on the other hand with the condition of the walls which enclose it, (extent of surface, permeability, duration of the affection).

5. In the general affections, the peptonuria seems to be connected with a disorganization *en masse* of the leucocytes.

6. In all cases, it is independent of albuminuria as well as the state of the temperature of the body.

7. Peptonuria suffices, in many affections, to account for certain clinical episodes; but its application to diagnosis is of value only in certain extremely restricted circumstances.

ON THE ELIMINATION OF MERCURY BY THE KIDNEYS.—Dr. Schuster (*Centralblatt f. die Med. Wissenschaft., Journal de Med.*) declares that the elimination of mercury takes place not only by the intestine, but also by the kidneys. It seems that this has heretofore been overlooked, owing to the want of use of proper reagents to detect mercury in the urine. Urine acidulated by hydrochloric acid and submitted to a current of sulphuretted hydrogen and then allowed to stand for twenty-four hours, will give a sediment containing sulphate of mercury, uric acid, mucus, etc. It is separated by filtration, and the sediment which remains in the filter, is treated with nitromuriatic acid and then dried until it no longer gives off the nitric acid vapors. The residue is dissolved in about 10 grammes of water, and, after being slightly acidulated, is treated according to the ordinary method of Fürbringer. By this method it is possible to detect $\frac{1}{10}$ of a milligramme of mercury in the urine.

The excretion of mercury after an ordinary treatment by friction continues for six months.

SCLEROSIS OF CARDIAC ORIGIN.—Dr. Jules Boy (*Marseille Medical, Journal de Médecine*) tells us:

1. That while we have a cardiac hepatic and cardiac renal sclerosis, we have also a cardiac pulmonary sclerosis.

2. That this pulmonary sclerosis is systematic and corresponds exactly to the changes found in the liver and kidney.

3. Diffused points of sclerosis are found, scattered throughout the parenchyma and accidentally produced.

4. This cirrhosis is characterized by a thickening of the peri and intra-lobular tissue, the thickening of the inter-alveolar partitions progressing so far as sometimes to obliterate the alveoli, by the dilatation of the vascular system with thickening of the tunica adventitia of the vessels, and by the constant presence of arterial lesions.

5. The principal changes are the stasis of blood and permanent dilatation of the vessels, a condition of the epithelium similar to Charcot's visceral epithelial cirrhoses, in the arterial system and in the dyscrasia.

RUPTURE OF AN ANEURISM OF THE CYSTIC ARTERY INTO THE GALL BLADDER.—Chiari (*Journ. de Med.*) gives the case of a man 33 years of age, who suffered for a long time from cardialgia, and died suddenly with intestinal hæmorrhage. At the autopsy a perforation of the superior portion of the duodenum was found, which communicated with the gall bladder by a sort of crossway bounded by the liver, the epiploon and the duodenum itself. The gall bladder contained some calculi and blood; on its hepatic wall there was a small aneurismal tumor 2 centimeters long, and 1 broad, that communicated with its cavity by a slit of 3 millimeters (superior cystic artery). A smaller bloody tumor, which was the seat of a thrombosis, was situated lower down on the gall bladder (inferior cystic artery). Medical literature mentions only four cases of rupture of aneurism of the hepatic artery into the bile passages.

A PULMONARY CAVITY HEALED BY INJECTIONS OF NITRATE OF SILVER.—In *El Siglio Medical* is recorded the case of a peasant of 26 years who contracted a pneumonia which passed into a chronic state and produced a purulent expectoration and an extreme emaciation. Dr. Maragliano determined the presence of a cavity at the base of the right lung. Judging all other medication to be useless he injected a gramme of nitrate of silver, dissolved in 25 grammes of distilled water. The pain was very acute for two hours, and then disappeared; the frequency of the pulse and the fever diminished. The expectoration increased for several days, but then diminished progressively and recovered its normal characteristics. One year later the cicatrization of the cavity was complete. A second case was similarly treated at Madrid, but with an unfavorable result.—*Journal de Médecine.*

EXPERIMENTAL RESEARCHES ON THE INJECTION OF MEDICINES INTO THE PULMONARY TISSUE.—Frankel (*Deutsch. Med. Wochenschrift*), seems from his experiments to have determined the fact of great tolerance

on the part of the lung to various irritating agents. He used solutions of 2 to 5 p. c. of acetate of alumina, 1 to 5 p. c. of carbolic acid, 5 p. c. of iodoform. The injections were made sometimes many times a day, sometimes at intervals of several days. Generally no functional reaction followed, in some exceptional cases there were paroxysms of coughing, but only when a bronchus was pierced, for the toleration of the pleura and parenchyma was complete. Anatomically there was found in the pleural cavity a coffee spoon full of blood, the pulmonary parenchyma being infiltrated with blood to the thickness of 1 centimeter; this being reabsorbed or undergoing a retrogression resulting in the formation of a slight cicatrix. The author considers that the results of these experiments would seem to authorize the employment of medical injections in phthisis where the process is localized and accessible; the diseased tissue undergoes a substitutive modification before hastening the work of cicatrization; in the neighborhood of deposits, a cicatricial zone is created which forms a rampart against the invasion of the process.

THE COST OF SICKNESS.—I think, then, that we can not escape from the reasons to believe that we lose in England and Wales, every year, in consequence of sickness, 20,000,000 weeks' work; or, say, as much work as 20,000,000 healthy people would do in a week.

The number is not easily grasped by the mind. It is equal to about one-fortieth part of the work done in each year by the whole population between 15 and 65 years old. Or, try to think of it in money. Rather more than half of it is lost by those whom the registrar-general names the domestic, the agricultural, and the industrial classes. There are more than 7,500,000 in number, and they lose about 11,000,000 weeks; say, for easy reckoning, at £1 a week; and here is a loss of \$11,000,000 sterling from what should be the annual wealth of the country. For the other classes, who are estimated as losing the other 9,000,000 weeks' work, it would be hard and unfair to make a guess in any known coin; for these include our great merchants, our judges and lawyers, and medical men, our statesmen, and chief legislators; they include our poets and writers of all kinds, musicians, painters, and philosophers; and our princes, who certainly do more for the wealth and welfare of the country than can be told in money.—*Sir James Paget, in Popular Science Monthly.*

EXIT OF SCIENTISTS FROM MONTREAL.

MONTREAL, CANADA, Sept. 4.—Two special trains left this morning, one having on board 300 British scientists bound for Philadelphia to attend the American Association meeting, and the other 200 scientists for the Rocky mountains. The presence of so large a number of eminent scientific men from Great Britain will add much to the interest of the meeting of the American Association for the Advancement of Science, now in session in Philadelphia.

THE
Journal of the American Medical Association.

PUBLISHED WEEKLY.

THE EDITOR of this JOURNAL would be glad to receive any items of general interest in regard to local events, or matters that it is desirable to call to the attention of the profession. Letters written for publication or containing items of information, should be accompanied by the writer's full name and address, although not necessarily to be published. All communications in regard to editorial work should be addressed to the Editor.

SUBSCRIPTION PRICE, INCLUDING POSTAGE.

PER ANNUM, IN ADVANCE..... \$5.00.
SINGLE COPIES..... 10 CENTS.

Subscriptions may begin at any date. The safest mode of remittance is by bank check or postal money order, drawn to the order of the undersigned. When neither is accessible, remittances may be made at the risk of the publishers, by forwarding in REGISTERED letters.

SATURDAY, SEPTEMBER 6, 1884.

HASTY GENERALIZATIONS.—Of all the faults that characterize medical literature, those arising from hasty generalizations, by which we mean the deduction of conclusions from an insufficient number or an inadequate verification of facts, are the most prominent, and constitute the greatest hindrances to real progress in nearly all the departments of medical science.

Next in baneful influence is the adoption and treatment of mere opinions or even suggestions, as though they were actual facts. From the simple facts that the elements of our food may be arranged, chemically, into nitrogenous and carbonaceous, and that the latter out of the living body are capable of uniting with oxygen and evolving heat, a Liebig announces the opinion that the nitrogenous elements of food are appropriated to the repair of the living tissues, and the carbonaceous to combustion and the support of temperature. Straightway this opinion is accepted, incorporated into our medical literature, and acted upon as implicitly and universally as though it had been the announcement of a clearly demonstrated fact. And yet it would puzzle the most erudite, even at this late day, to point out any facts which prove that the two classes of alimentary elements play any such separate role in the living body as has been assigned to them.

Cases of an epidemic disease make their appearance in a given locality, and instead of patiently waiting until their origin, or at least all the ascertainable facts connected therewith, can be carefully investigated and placed on record, every writer and

speaker at once *suggests* an origin which will suit his preconceived theories concerning the nature of the disease, often entirely regardless of all the actual facts in the case. And yet these naked suggestions are accepted, incorporated with the history of the epidemic in medical journals, and ultimately quoted in standard works, invested with all the attributes of established facts of science. The appearance of the present cholera epidemic in Toulon affords a good example of the practice we are deprecating. When the outbreak was first announced, it was represented as having started in the oldest, most filthy part of the city, and among the most destitute and unsanitary part of the population. Not a word was said about its connection with ships or sailors from any quarter. Next, however, it was stated to have been brought in some naval vessel from Tonquin or some port of China. But no facts were given to show that the accused vessel had actually come from a place where cholera was prevailing, or that any cases had occurred on board, either before her arrival or afterwards. Next, Dr. Koch is reported as making the rather ungracious remark that it was introduced by some English vessel whose officers had falsified her bill of health. And finally, we have the positive and circumstantial report that the two first cases at Toulon, occurred in marines who had been employed in removing some materials or rubbish from an old hulk in the harbor which had lain undisturbed since the return from the siege of Sebastopol in 1856; it being presumed that the germs of the disease had been slumbering there in undisturbed concealment during all the intervening twenty-eight years. And yet since the first *suggestion* concerning the importation of the disease on some ship, almost every writer, both in the secular and medical press, has assumed that such importation took place with as much positiveness, as if each step in the process had been fully identified by actual investigation of all the facts bearing on the case.

In the natural order of events these *assumptions* in the present current literature will be quoted as facts by the historians and investigators of the next generation. Again Dr. Koch, after finding a number of microbes of different varieties in the intestines and intestinal dejections of cholera patients, selects one which he suggests, after a limited number of post-mortem examinations, is peculiar to and causative of the disease. His suggestion that this particular comma bacillus or spirillum is *always* present in the intestines of epidemic cholera patients, and not in those of patients affected with any other form of disease, is accepted by a large part of the profession

with as much apparent confidence as though it had been possible for Dr. Koch, or any other one man, since he first entered upon his cholera investigations in Egypt little more than one year since, to have examined not only an adequate number of cases of cholera, but also of such number and variety of other diseases, as to justify both the positive and negative part of his suggestion. The finding of a particular microbe in the intestines of one hundred consecutive cases of epidemic cholera, would go far to prove that such microbe was always present in that form of disease, not necessarily as a cause, but certainly as an accompaniment.

But to assert that the same microbe is found in no other form of disease, presumes a scope of actual post-mortem and microscopical investigation that would occupy one man nearer a life-time than the short space of a single year.

Indeed such investigations can never conduct us to actually reliable results until they have been repeated by numerous qualified observers, in several epidemics, in different localities, and also in a wide circle of collateral diseases.

We do not disparage, but honor Dr. Koch and all other skillful investigators in the different departments of science; but we are getting well-nigh weary with half a century of experience in the process of unlearning one year what we thought we had learned the year previous, and of seeing the time of one-half of the world's investigators consumed in disproving and correcting the too hasty deductions of the other half. Our professional and scientific investigators, and indeed the whole profession, need more industry in the observance and aggregation of facts, more logical study of their relations when aggregated, and far more patience and caution in the deduction of important conclusions which are to influence both our dealings with disease at the bed-side of the sick, and guide our efforts to afford sanitary protection to communities and nations.

INTERNATIONAL MEDICAL CONGRESS AT COPENHAGEN.—At the recent meeting of this great international organization, there appears to have been present a very fair representation from the profession of our country. Among them were several who read papers in some of the Sections. In the Section of General Pathology and Pathological Anatomy, Dr. Samuel N. Nelson presented a paper on the "Cultures of the Micrococcus of Diphtheria;" in the Section of Medicine, Prof. Austin Flint, of New York, had a communication "On a Uniform Nomenclature

of Auscultatory Sounds in the Diagnosis of Diseases of the Chest;" in the Section of Surgery, Prof. Sayre, of New York, demonstrated the application of the plaster jacket in the treatment of diseases and deformities of the spine; in the Section of Obstetrics and Gynæcology was announced a paper "On a New Operation for the Restoration of the Ruptured Perinæum," by Dr. Henry O. Marcy, of Boston; in that of Ophthalmology, a paper on Ocular Therapeutics, by Dr. W. Seely, of Cincinnati; in that of Laryngology, a paper on the Prognostic Significance of the Several Local Manifestations Observed in Tuberculosis of the Larynx, by Dr. Solis Cohen, of Philadelphia; one on the Operative Removal of Foreign Bodies and Pseudoplasms from the Air-Passages, by Dr. Lefferts, of New York, and another on the Proper Method of Training of the Singing Voice, by Dr. Bosworth, of New York; in the Section of Otology, a paper on the Diagnosis of Inter-Cranial Complications in Suppurative Inflammation of the Middle-Ear, by Dr. Orme-Green, of Boston; and in the Section of Dermatology and Syphilis, a paper on New Methods and Remedies in the Treatment of Diseases of the Skin, by Dr. J. V. Shoemaker, of Philadelphia.

An abstract of the last paper may be found in another part of this number of the JOURNAL. The principal languages used in the papers and discussions were the French, German and English. A brief account of the general scientific and social features of the assemblage will be found under the head of Foreign Correspondence.

YELLOW FEVER.—This justly dreaded disease continues to prevail severely in several places in Mexico, Central America, and the West Indies, but thus far appears to have become prevalent in no part of our own country. Its position in Mexico is such as to create constant apprehension in the adjoining parts of Texas. The case that occurred in one of the ports of Florida has been followed by no others, and the same result has followed the reported cases at other ports.

PROGRESS OF THE CHOLERA IN EUROPE.—During the last week the epidemic appears to have increased more rapidly than before, and is now prevailing not only in the south part of France, but in many parts of Italy and Spain. Its progress northward, however, is slow.

THE American Public Health Association holds its next annual meeting in St. Louis, Mo., commencing October 14, and continuing to the 17th, 1884.

THE American Pharmaceutical Association has just closed a well attended and interesting annual meeting in Milwaukee, Wis. The following officers were elected for the ensuing year: President, Henry Conning, of Boston; Vice-Presidents, Lucius Lybrand, Nobleville, Ind.; J. B. Bond, Little Rock, Ark.; Charles A. Heinitsch, Lancaster, Pa.; Secretary, J. W. Colcord, Lynn, Mass.; Treasurer, J. D. Wells, of Cincinnati, Ohio.

DEATHS.—Charles Walter Chamberlain, M.D., of Hartford, Conn., Secretary of the Connecticut State Board of Health, died on the 21st of August, 1884, aged 40 years.

Dr. Grafton Tyler, of Georgetown, one of the oldest and most popular physicians in the District of Columbia, died on the 26th of August, 1884.

THE Medical Association of the Mississippi Valley holds its next anniversary meeting in Springfield, Ill., commencing on Tuesday, Sept. 23, 1884. This organization was formerly known as the Tri-State Medical Society. Let all interested remember that the time of meeting is near at hand.

THE British Association for the Advancement of Science has just closed an apparently profitable and satisfactory annual meeting in Montreal, Canada. Many important papers were read and discussed, and the social arrangements were pleasant and well executed.

SOCIETY PROCEEDINGS.

BOSTON GYNÆCOLOGICAL SOCIETY

REGULAR MARCH MEETING—H. O. MARCY, M.D., PRESIDENT, IN THE CHAIR; HENRY M. FIELD, M.D., SECRETARY.

The report of last meeting having been read and approved, Dr. Field remarked upon the extraordinary contrast presented by eclampsia puerp. in women and in the cow as determined by three statements in Dr. Billing's paper (V. Febr. session); to the effect that (1) associated with the convulsions or their representative in the cow was an exceptionally contracted state of the uterus; that (2) the disease seldom appeared till after the expulsion of the secundines; and (3) that it seldom accompanied first parturitions or later deliveries but was apt to attend the third, fourth, or fifth in contradistinction with the first or second, or with the seventh or eighth. All this is surely quite different from what we are accustomed to observe in the human female.

The committee appointed for the purpose presented resolutions upon the death of Professor Ercoiani, of Bologna, an honorary member of the society, which, having been accepted, the Secretary was instructed to have properly written out and forwarded to the family of the deceased.

H. C. White, M.D., presented a communication on the subject of a New Method in the Treatment of Recto-vaginal Fistula.

Patient, a female, was aet. 26 years, and had had two children of, respectively, 26 and 10 mos. Herself one of two children, her mother and brother died early of consumption. When 16 years of age, she was thrown from a horse, leaving a permanent weakness low down in the back, and a tendency to discharge, which was believed to be leucorrhœal. A year later had a small abscess on left vulva, leaving ever after occasional attacks of soreness in that locality. During her first pregnancy, when about 21, had two abscesses in perineal region, which were left to take care of themselves under homœopathic supervision. A second pregnancy followed closely on the first, and soon after its inception patient began to suffer seriously in the perineal region. Dr. W., having been called in, found a fistula discharging from the left labium, accompanied by a great amount of inflammation. Her condition and suffering prevented a further examination at that time. Discharge continued constantly up, and subsequent to the birth of the child. Babe was weaned at eight months, and two months later an operation was performed, which was done in January last by Dr. Marcy, assisted by Drs. White and Nelson.

The perineal body was found to be small and contracted by a considerable laceration at childbirth. The opening in the labium was found to communicate with two sinuses in the rectum, $1\frac{1}{2}$ to $2\frac{1}{2}$ inches long, respectively. After the fistulæ had been cut through, completely dissecting the sphincter inside and opening far up into the rectum, the canal of the fistulæ and sinuses was removed, the membrane being carefully dissected out with scissors. The skin was then dissected back from the right side of the perinæum, the mucous membrane of the rectum was carefully brought together at the line of its division, with the over and over stitch—a fine tendon suture being used—and the cut surfaces were brought into apposition and secured by the perineal pins devised by Dr. M. for operations for laceration of the perinæum. Very slight increase of temperature followed the operation. The pins were removed after eight days, and patient made a good recovery. Wound now (March 10), well healed, sphincter well contracted—has had no trouble in retaining her fæces; has gained in flesh. There are now no symptoms of any fistula.

At the close of Dr. White's communication, Dr. Marcy made brief remarks in farther explanation of the operation and called upon Dr. Pines, present by invitation, for an expression of his opinion; who said, in effect, that the operative procedure, was a new thing in his experience.

Dr. Marcy hereupon read a paper upon *The Relations of Micro-organisms to Surgery*. He first gave a

careful review of the evidence upon which the belief was founded of the deleterious effects of germs upon wounds and, through them, upon the general organism. He stated that much remained unsettled, and that many questions of great importance were still in active discussion. However, it was beyond dispute that sufficient had been determined in a positive manner, so that we may no longer doubt the fundamental basis of truth from which the modern system of wound treatment had been evolved.

The criticisms of abstract theory and practice are no longer pertinent with its objectors, and something more absolute and tangible must be advanced in argument from the other side. Anything may be doubted. There are many who would not accept the demonstration of any historic fact, and every mathematical formulation or axiomatic truth would by some be questioned.

The discussion of what constitutes a poison to wounds was entered upon, and the various exposures detailed to which open wounds are liable. Accepted that a subcutaneous wound, without necrosis of tissue, was the condition most favorable to repair, the comparison therewith of other wounds, in various conditions, was made, and the factors detrimental to repair were analyzed and compared. The most important indication in wound-treatment is to secure an aseptic condition, which may be defined as a wound surgically clean.

The individual, vital force must ever be the first factor in consideration; and this is variously modified by conditions extraneous, such as race, age, idiosyncrasies, mental state, constitutional conditions, disease, surroundings, etc. The bioplastic force, however denominated, is the force to be relied upon in restoring the equilibrium in the injured organism. Good sanitation aids in the recuperation of this power.

All this has long been known by the surgeons of past generations, and more or less effectually they have armed to secure these desiderata. The enunciation of the particulate theory of fermentation was the first step in advance and, upon its demonstration, a great revolution in the treatment of wounds began which has already given most brilliant results, and the farther promise of greater good than any innovation since medicine became an art.

The Greek word *σέπτικος* signifies that which causes putrefaction, and, per consequence, antiseptic can have but one meaning, viz.: that which is directed against the cause, not the effect, of putrefaction. Granting that putrefaction cannot occur without fermentation and that fermentation is brought about by the growth of the spore-producing plants, it is a simple thing to formulate the role of micro-organisms and to trace to them, as the *causa causans* many of the most deleterious results incident to wounds.

Defects of bioplastic power, both constitutional and local, result in disorders of repair; defects of apposition prolong the process and make extra demands for reparative material; but, in defects of protection, are found the conditions which produce arrest of reproduction and destruction of the adjacent tissues. The disturbing elements, arising from atmos-

pheric contact, come only from the organic, living particles held in suspension.

The forms of germs which produce fermentation may be classified under three general types; viz.: the micrococcus, the bacterium and the yeast-cell. Only the first two are important in their relation to wounds. Both these forms are generally found in open wounds. With micrococci alone, decomposition proceeds without odor. The reproduction of bacilli is accompanied with odor more or less foetid; bacilli are comparatively easy of destruction. The question of pathogenic germs of greatly varying types is one still *sub judice*.

Experimental proof is constantly accumulating to show that the inflammatory and other changes, which ensue in wounds, are, with few exceptions, the result of the vital activity of new organisms. There is abundant evidence to show the extreme probability, at least, that septicæmia and pyæmia are one and the same disease, and that their sole and invariable cause is due to micrococcus poisoning.

The superficial opinion of many physicians, who are daily engaged in the treatment of wounds in the time-honored manner of their fathers, is to the effect that Listerism and antiseptic surgery consists only in the application of carbolic acid to a wound, in the form of spray or otherwise, while they are still in ignorance of the broad, scientific, fundamental knowledge upon which the modern methods of wound-treatment are based.

Dr. Martin opened the discussion which followed Dr. Marcy's paper. He would first call attention to the fact that the so-called antiseptic agents used in Listerian dressings were not germicidal, and, therefore, can have no effect upon the bacteria which may be present in the wound. He objected to the reasoning that because the results of work in accordance with a theory are better than results formerly obtained, therefore the theory is correct. He thought many physicians still used carbolic acid because they were afraid to oppose the accepted practice.

Dr. Nelson called attention to and explained the elaborate experiments carried out by Dr. Marcy and himself in demonstrating the efficiency of germicides.

Dr. H. C. White said he had been lately treating certain diseases, such as typhoid fever and scarlatina, with sulphurous acid, assuming that they were due to germs, and had been much pleased with results.

Dr. Martin objected that germs existed in the body *de novo*, and that sulphurous acid could have no power to destroy them in the tissues. If a piece of healthy lung tissue was rapidly removed from an animal and at once dropped into boiling oil, so as to form an impervious coating, bacteria would still be found in its interior.

Dr. Marcy, in reply, did not admit that bacteria existed in healthy living tissues. Was not able to explain the existence of bacteria in cysts. Cited the case of rupture of a cyst of size of a walnut into the abdominal cavity, and death in thirty-six hours. The fluid in the peritoneal cavity was found to be swarming with bacteria. Believed that death was due to the rapid multiplication of germs introduced into the system from the cyst. Dermoid cysts are full of bac-

teria, and these, when let loose by opening the cyst, are a source of great danger. This danger lies in the absorption by the newly-cut surface, not by the walls of the cyst. Bacteria are a cause of decomposition, not a result.

Dr. Martin insisted that two things had ruined the profession, viz., theory and reasoning from analogy. Because of observations in two diseases—one of which we produce ourselves, *i. e.*, in charbon and vaccinia—we have jumped to the conclusion that every disease is referable to a germ. In three years more as much will be claimed of cancer as it is already in respect of diabetes. Within fifty years the Listerian theory will be an exploded delusion; this he had been accustomed to say, but since he had seen Prof. Lister himself and his methods, he had reduced the period to twenty-five years.

As he had stated on previous occasions, he had punctured the knee-joint nearly 600 times, with no trouble whatever, and yet he had never used antiseptics. Dr. Mary P. Jacobi had lately written on the fatality of opening a dermoid cyst by aspiration, and this notwithstanding every precaution taken in antiseptics. "I say," continued Dr. M., "if these cysts had been punctured with a clean needle, untouched by caustic fluid, better results would have followed."

Furthermore, carbolic acid, as used, cannot do any harm to the germ. Would ask, In what way do bacteria do harm? Is it by their local presence or their presence in the circulation? Unquestionably, in the latter way; and if this is so, what good can a little rag do, wet in carbolic acid and applied to the wound? What infinite harm will this powerful agent do, if introduced into the general circulation in sufficient quantity and potency to destroy the germs therein disseminated. Take as an example operations upon the rectum. Dr. M. had never in his experience had a fatal case. It is well known that in this region abscesses form which are likely to lead to fistulæ. When first opened they are horribly putrid, but after free discharge has taken place all putridity ceases. He would ask for an explanation of this fact, in accordance with the principles professed by the author of the paper.

Only the other day he had opened a large perinephritic abscess. The smell at first was simply horrible. He threw in hot water in liberal quantities to the evacuated cavity, and in 24 hours all foul odor had left the discharge. The thousands of wounds that have been made by paracentesis of various cavities; the millions of wounds of all kinds made every day—what of these! Why do not they admit the bacilli? They are even more open to them than is the surface of an amputated thigh, because the latter is protected from the first with various wrappings and bandages. Whether we cover with cotton or with carbolized cotton, we shall find that the result is the same.

The Germans and Scotch, beyond all other people, have crowded our literature and art with wild theory, and with results which, while they show great intellect and labor, are too often of but slight practical value. They are great students and investigators. A moment's reflection upon the history of medicine

will prove this to be true. Those who have had the great pleasure to meet and converse with Mr., now Sir Joseph, Lister, are well aware that in him the Scotch theatric, metaphysical element is by no means lacking. To his keen, shrewd, untiring observation, perseverance and common sense we owe an immense advance in surgical methods, the redemption of surgical practice in hospitals from the charges which Sir Jas. Y. Simpson brought against it, we all know how justly.

"I make no objection," continued Dr. M., "to the *Listerian method*. What there may be of redundancy, of superfluity, of actual danger to the surgeon as well as patient, in its connection will slowly but surely cure itself. And, indeed, Sir Joseph's practical abandonment of the spray is proof of this." Most that is valuable has come to us through the attempt to vindicate in practice the truth of theory. If the success of the complicated system termed the "*Listerian method*," is, as Sir Joseph claims it is, proof positive of the truth of the theory, then it is very important that it should be proved, as it most surely has not yet been. If, as I maintain, the success of the Listerian practice is no proof whatever of the truth of the theory of germs and germicides, it is most important it should be known. *Palmarum qui meruit ferat!* On Mr. L's instantly evolved theory there was builded a system in one night, as it were.

From Germany and Scotland have come the greatest number of wild theories, and also of solid results of close, intelligent and laborious investigation and study in our art. From the Teutonic race have come the theories of Stahl, of Hahnemann, of Sylvius, of Paracelsus, as well as the admirable researches of Rudolph, of Haller, of Virchow. From Scotland, we have the theories of Cullen, of Brown, and we have, too, the results of the wonderful genius and labor of the two Hunters, of Ferguson, of Brodie, and of a host of others. Those who have had the great favor and benefit of meeting Sir Joseph Lister in person know very well that with all his merit as a practical surgeon, the metaphysical, theoretical element is by no means lacking in his temperament. To that we owe his invention and advocacy of germs and germicides; to his sound, practical Scottish sagacity and common sense we owe the great and invaluable improvement he has made in surgical methods. Whether I am right in this or not, Sir J. Lister certainly evolved the germ theory, as applied to purely surgical disease, in the quiet of his study with Pasteur's book open before him. Like the fully armed Minerva from the brain of Jupiter; like the theory of Hahnemann in his poor garret study with a volume of Cullen's *Materia Medica* on his desk; like the German students' camel; like Carlyle's *Kubla Khan*, in waking from a sleep into which he had fallen over *Purdias his Pilgrimage* on his knee; like all such things, this thing was evolved from the inner consciousness of the inventor, and in a night, as it were. Mr. L. has had many bad results, but they were not allowed to appear in his wards.

Dr. M. again alluded to the problem he had recently proposed in respect of the period in which decomposing animal matter is capable of communicating disease, such material being innocuous before

and after; speaking on this subject in some detail, and would again demand, as he had demanded before, how such facts can consist with the Listerian theory. Again, in dissection wounds, the fatal symptoms do not take nine days in which to show themselves, the case is distinctly declared at the end of forty-eight hours. The horribly smelling pus of abscesses formed in recondite parts of the body, with which all are familiar—what has the germ theory and Listerism to do with this? It is said that it is the germ in the interior of the body that does the harm, and this I know, continued Dr. M.—but to reach and destroy the bacteria in the interior of the body it will take a dose of the latest fashionable disinfectant, *corros. sublimate*, that will kill the patient too.

Lister began by excluding drainage, but now he is the most exact and rigid man, in respect of drainage, that lives; just here he shows that he is an admirable surgeon. Here, as also in winding a strangulating bandage about the stump, he has done a great deal of good. He has reformed the entire system of surgery, as said before, but not one iota of credit belongs to his germs or to the theories he has built upon them!

Dr. Pines, upon call, thanked the Chair for invitation to be present at the hearing of a subject of so great interest as that presented both by the paper of the day and by Dr. Martin's remarks upon the same. Dr. M. had shown himself pervaded by that philosophical scepticism which the Germans say lies at the foundation of all science. In his own practice of forty years, he had learned to be sceptical both in the use of new remedies and as respects adherence to new methods. Could well remember he was accustomed to observe, full thirty years ago, that wounds that were cared for in a cleanly way were pretty sure to do well. We did not hear of septicæmia then as now, and it may well be that this comparatively new condition has become a bug-bear with the profession for which we are disposed to seek out new remedies. It used to be the general opinion that the best method with abscesses was to open freely to the air, letting nature have her way outward, and I do not remember that, thus doing, we used to have serious trouble from germ poisoning.

Dr. P. continued to the effect that when Listerism was first brought forward he recognized the fact that it would at least secure a superior degree of cleanliness in wound-treatment; and he had seen that those who follow this method are steadily diminishing the amount of carbolic acid they use, until its strength in their washings and lotions begins to approach homœopathic potency. In one word, we have been brought to the perfection of surgical cleanliness.

Dr. Martin recalled the vast number of men, during the late war, brought into division hospitals with various wounds, already suppurating and pululating with maggots; but these subjects did remarkably well, certainly before they were put into the hospital and sometimes afterward. Perhaps the maggots served as germicides,—assuredly the soldier had no other protection against the germs about which we hear so much to-day.

Upon call for pathological specimens, Vice-President Norris took the chair, and Dr. Marcy exhibited

a multilocular ovarian cyst which he had removed four days previously. Patient æt. 52 years. Menses ceased six years before. Had noticed a lump in left side seven years before, but it had not been troublesome till about six months ago. Since then had suffered much pain, but general health was good. Considerable amount of ascitic fluid. Cyst, 9 lbs. in weight, was everywhere adherent, to parietes, to omentum, and in some places to the intestine.

Several of the cysts were ruptured in the removal. Pedicle secured by tendinous suture, shoemaker's stitch, and the divided peritonæum approximated over the stump by continuous suture, and returned to place. Other ovary cystic, tube enlarged,—both removed. Shock severe and prolonged, although the rectal temperature; when put to bed, was 99. Temperature before operation normal. Rallied slowly, no pain or nausea. After 48 hours albumen and casts, granular and hyaline, apparent in urine, which was of low specific gravity and scanty. Death occurred on the third day, after almost entire suppression of urine.

Autopsy.—No hæmorrhage, no general peritonitis; $\frac{3}{4}$ oz. red serum in Douglass' fossa, swarming with active micrococci and bacilli. Kidneys pale, flabby, capsule adherent in places; in tubules were found both micrococci and bacilli. Cause of death, septic nephritis. The operation was done under careful aseptic precautions, but in the unopened smaller cysts were found active organisms similar to those in the kidney and retro-uterine fossa.

Dr. Marcy also gave the history of a case where death had occurred about forty-eight hours after the spontaneous rupture of an ovarian cyst not larger than a large walnut. In the thick molasses-colored fluid of the cyst there were very large and numerous bacilli, which was the presumed cause of the septic peritonitis. The doctor had not found any allusion to the existence of micro-organisms in cysts of the ovary, but believed they were commonly present in dermoid cysts; was unable to explain their origin.

Dr. M. also exhibited the ovaries and tubes removed from a patient the day before. Widow, over 40, never pregnant, well until four years ago. Since then, severe pain in the pelvis had been a constant factor, with occasional menorrhagia, so pronounced as often to demand the tampon. Patient was sent to him by Dr. A. Young, of Prescott, Wis., with statement in letter introducing her that he had never seen a more pitiable sufferer. Diagnosis, disease of the ovaries and tubes with a small fibroid tumor.

Operation, without complication, confirmed the diagnosis. Sub-peritoneal, pediculated myoma of size of English walnut; refrained from its removal. Tubes much enlarged and convoluted. Slight cystic degeneration of ovaries, with adhesion of right ovary. (Under date of March 20, Dr. M. reports convalescence without complication.)

Dr. M. also exhibited the cotyledons from a cow, which he had removed, having been detained over night at the house of a farmer when at a consultation visit in the country recently. Cow, 15 years old, had been delivered of a dead calf four days before; hæmorrhage so severe as to threaten death, animal very weak. Had removed with much difficulty a

placenta composed of 30 to 40 cotyledons, each firmly adherent. Decomposition had already set in and the entire mass about half filled a pail.

Dr. Warner suggested that the fibroid, in one of Dr. Marcy's cases, might have been the cause of the hæmorrhage. Reply: This could hardly have been, as the fibroid was attached externally. Still, persisted Dr. W., the pedicle would be likely to penetrate to the mucous membrane of the cavity and so set up an excitation leading to hæmorrhage. Dr. M. replied that his studies, so far as he had pursued them, would hardly warrant any such conclusion.

Dr. Wheeler asked what killed the patient in the second case reported. Dr. Marcy replied that, in his belief, it was septicæmia. Dr. Martin asked if the urine had been examined prior to the operation. Reply: It had. Dr. Nelson had examined the specimen microscopically and found it full of micrococci.

Dr. Wheeler remarked: It was formerly believed septicæmia did not appear at so early a date, but he thought this view was now abandoned, and Dr. Marcy's experience in the case reported, gives confirmation in this direction. He had himself had similar experience.

Society adjourned.

INTERNATIONAL MEDICAL CONGRESS.—ABSTRACT OF A PAPER ON NOVEL MEANS AND METHODS IN THE TREATMENT OF DISEASES OF THE SKIN.

BY JOHN V. SHOEMAKER, A.M. M.D.

Lecturer on Dermatology at the Jefferson Medical College, and Instructor thereon in the Postgraduate course of that Institution. Physician to the Philadelphia Hospital for Skin Diseases, etc.

[Read before the Section of Dermatology of the International Medical Congress at Copenhagen, Denmark, Aug. 12, 1884.]

After dwelling on the old routine treatment of skin diseases, the writer enumerates the changes and practical results attained by modern remedies enumerating Naphthol, Pyrogallic acid and Chrysarobin instead of the tar treatment of old; the oleates with their penetrating power as solutions to enter the glands and follicles in contrast to the older remedies which as suspensions only reached no further than the epidermal layer. He states that favus without epilation may be now cured by mercuric oleate, or copper oleate; that Trychophytosis is readily subdued by similar means, and that chromophytosis is readily cured by the latter. Arsenic and mercury are now better administered subcutaneously than formerly per orem, and that the latter had almost superseded the old inunction treatment.

He enters principally into an account of those novel means and methods which he had himself developed and been able to observe and study.

After entering into a special review of the oleates he called attention, based upon physiological experiments, to the fact that they produce little if any constitutional effect, that they do not enter into the blood

and are not found in the excretions, but claims for them a better contact action than by the ointments of old, from the fact that by their solubility in fatty vehicles they are capable of entering the glands and follicles, and cites their use in the different affections, calling attention to many new ones not heretofore in use, such as mercurous, nickel and tin oleates. As a novel remedy developed by him, he refers to chlorinated oil, which, devoid of odor or irritant properties, he has formed a most serviceable remedy in scabies.

The oil of Ergot first recommended by him, he quotes as a most effectual remedy in seborrhœa of the scalp and other hairy parts of the body, for which it is far preferable to other fats and oils. In seborrhœa of the genitals he found it especially serviceable and recommends it as a hair oil for cases of idiopathic loss of hair resulting from lack of tone of the follicle. He also refers to the use of soap bark as a substitute for soap, especially as detergent for the scalp and its tincture as a mild substitute for the spiritus saponis kalinus.

In scrofuloderma he had found the hypodermatic use of Cod Liver Oil as more reliable than the internal use of it, which is often either omitted by the patient, or, if taken, not assimilated.

In reviewing the Beta Naphthol he speaks of it with much praise, and after citing interesting experiments to test the toxic effect claimed for it, he finds that if properly prepared, freed from its volatile odorous principles, it is certainly devoid of any such property, while it undoubtedly proves the most effective remedy in scabies and one of the best in psoriasis; taking the place of the unsightly and unpleasant tar, and mentions its favorable action in eczema, etc.

The accounts of his use in diseases of the skin of the infusion of the jequirity forms one of the most important points of the paper. Deducing from its use in granulating lids that it might have a similar action on granulating conditions of the skin, he had applied it to cases of specific scrofulous and epithelial ulcers and obstinate ulcers generally, and from an experience with it in a year was so gratified with the results that he recommends and endorses the use thereof in all such conditions. He employed a 25 pr. c. infusion, which was made by macerating the decorticated cotyledons and rubbing them up, allowing the pulp to remain therein.

Describing the manner in which the specific jequirity inflammation develops itself, he cites various cases in which, after other means had failed, this infusion alone had been able to effect cures. While calling attention to the fact that it may at times produce unpleasant symptoms, he states that he had at no time seen serious consequences follow its use.

Speaking of mechanical remedies, the writer describes them in a general way, and enumerates them as, 1st, massage; 2d, compression; 3d, blood-letting; 4th, incision; 5th, excision; 6th, enucleation; 7th, scooping; 8th, scraping; 9th, the seton, and 10th, cauterization. While not claiming them as new in their manner and character, he refers to them as being neglected by the practitioner, though of great use and value. Massage he recommends both for its constitutional and local effect. The former to insure

passive motion when it cannot be performed actively, as well as by promoting oxidation so necessary in psoriasis, as well as in other affections when it is necessary to carry off effete products, and also in neuralgia, perverted sensibility and trophic disturbances of the skin. He also recommends it in chronic and sub-acute forms of eczema to remove deposits and infiltrations. In seborrhoea he also finds it useful as well as in indurated acne glandular swelling, and in excessive and deficient pigmentation of the skin. Compression he refers to as indicated when support is wanting by means of any substance giving rest to the affected parts. He recommends it in eczema, especially when involving the abdomen, nates and genitals. It thus prevents friction, relieves congestions and he claims it as a useful adjuvant in certain eruptive fevers, the œdema after erysipelas, eczema, furuncular and glandular affections, herpes, herpes zoster and urticaria. Blood-letting he considers as efficacious both for local and general effect. As an antiphlogistic it is of great value, especially in chronic eczema, to assist the action of constitutional remedies. Topical blood-letting by either puncturing, scarification and leeching, is of the greatest importance to relieve the engorged cutaneous vessels in the various inflammations of the skin. Venesection as constitutional means, proves most valuable in certain cutaneous eruptions occurring in plethoric subjects. Incision made for the purpose of exposing, dividing and removing the parts is at times of great importance to relieve tension of the integument, divide sensitive nerves and give vent to pent up inflammatory products, and is useful in sycosis, rosacea, erysipelas, boils and carbuncles. Excision for the removal of morbid parts, both by knife, ligature or crushing, is spoken of as often of absolute necessity, while enucleation to remove diseased structures after incision into skin and capsules would come under the same heading. Scooping, scraping and cauterization are treated by the author in a like manner for the purpose of destructive action on diseased and neoplastic developments, particularly the latter, either through heated mediums or the lens and solar rays, are recommended for that purpose.

The writer in closing, points out that the means and methods referred to have been of great use to him, and if confirmed by others they would certainly form an important addition to our knowledge of the therapeutics of dermatology.

PASTEUR'S experiments with the virus of rabies have been investigated by a committee appointed to inquire into the reality of the protection afforded against hydrophobia. This committee has entirely verified his conclusions. Of 23 dogs which were submitted as protected all have been found proof against inoculation with the virus of rabies, whilst of eight unprotected dogs on which intra-venous inoculation was performed, and five unprotected ones which underwent trepanning and inoculation, all became mad.

June is usually one of the healthiest months in the year when there are comparatively few deaths from zymotic diseases, for the reason probably that the people are so much more out of doors. Then the changeable spring weather that has played such sad havoc among the consumptives and the weakly generally, and has been so unfavorable to all kinds of diseases of the air passages and respiratory system, has given place to a warmer temperature and less fickle changes. This year, however, while the prevalence of lung fever and fatal fevers have been less than has been the rule for the past few years, the lighter fevers and especially influenza have been more than ordinarily common. Thus from Willington almost an epidemic of influenza is reported and many cases of throat trouble, and to a less degree the same, especially the catarrhal and throat troubles is true generally. Whooping cough has been very prevalent, Hartford, Norwalk, Stafford Springs, New Hartford, Willimantic, Waterbury, and in a portion of Ridgefield, which indicates its diffusion. Scarlet fever ranks next. After a marked decline and total disappearance in many places it has reappeared in considerable virulence. The table shows its mortality in the cities. Two deaths are reported from Willimantic; seven cases, three fatal are also reported from South Manchester; cases usually severe are reported from several towns in the southwestern part of the State. The indications are that the disease is spreading and is rather increasing.

Diphtheria is less prevalent than in the spring but shows a slight increase over last month. It still lin-

gers in Hartford. The deaths, eight in number, are just double the total mortality in Bridgeport in 1833 from diphtheria, although that city before the efficient sanitary work done of late, used to report 75 or more deaths for a series of years. Four deaths are reported from Willimantic, and cases usually of a not very malignant type are reported from eight towns. The prevalence of these diseases is unusual for June, unless an epidemic exists. In most of the cases filth conditions are easily traceable. The overflow of filth from the soil pipe on the lower floor of a three-story tenement house, and a broken earthenware outlet pipe from the house to the sewer were associated with five deaths, and sink drainage percolating through a cellar wall, with two others; faulty plumbing with the greater part of those in the cities.

Each month that reports are made of causes affords more or less clear instances of the relation between filth and diphtheria. So constantly has this been noted that the Massachusetts State Board of Health in a recent circular affirm that diphtheria can be caused by filth directly without any connection with a preceding case.

Diarrhœal diseases have not been as prevalent as was indicated by their early appearance. Several cases of sudden death, both in children and adults, have been reported, death ensuing 24 and 36 hours after seizure. A few cases of dysentery have been reported, but only in one locality.

Malarial diseases are reported as increasing in the southwestern part of the State and along the valley of the Connecticut. Fevers, intermittent and remittent, are reported from Tariffville, while the month is declared to have been the healthiest of the last twelve, with little other sickness. A similar report is made from Oxford, that is, no sickness except an increase in malarial disease. Typho-malarial fever is also reported in several cases.

In general, the history of the month has not been as unfavorable to health as the average, while more so than is the case usually in June. Cheshire reports one death only, Granby but three, one from old age. Haddam is reported unusually healthy, and whooping-cough and measles as the only diseases prevalent in Stafford Springs. Ridgefield is pronounced unusually free from disease, and the same, with the exception of malarial diseases, could be said of several places.

Nervous diseases have been unusually prominent for June. Thus, New Haven reports 23 deaths, 16 from convulsions, and in many towns cases of meningitis and cerebro-spinal meningitis are reported. These are all in the part of the State where malaria has long been prevalent. That there is some causal relation in case of cerebro-spinal meningitis is more than probable. The relation to nervous diseases in general is certainly quite constant.

A fatal case of sunstroke is reported from Waterbury; one not fatal from Somers, while instances of persons overcome by the heat or partial sunstroke were oftener mentioned. The table indicates an unusual number of accidental deaths. To these must be added two from South Manchester, one from drowning, one from a broken back.

FOREIGN CORRESPONDENCE.

LONDON, August.

At the distribution of prizes and certificates to the students of St. Thomas's Hospital, the Archbishop of Canterbury, in acknowledging a vote of thanks, said that he felt great pleasure in the bond of union which existed between Lambeth Palace and St. Thomas's Hospital, and the use which the students were able to make of the Palace fields for their football, cricket and other sports. He was delighted to see how far-reaching the hospital was. It was not simply an institution, but a great nest of institutions. The human organism was one of God's greatest works, and the study of forces and influences must be to them, if they saw below the surface, a great revelation of the name of God. He had read the other day what the character of a good physician and a good surgeon ought to be, and the qualities which he should possess were courage and presence of mind, deep sympathy, perfect candor, simple manners, clear faculties, and pure moral feeling, and if over all there was shed the light of God they would have in the man who possessed them one who was qualified alike to work and to teach. Mr. Labouchere, in his journal, *Truth*, commenting upon the Archbishop's speech, hopes that if he is ever taken suddenly ill his friends will not trouble to find such a man, but trusts they will bring the nearest practitioner, for fear he should die before the good physician could be summoned to his help. A Japanese gentleman was successful in taking a prize and scholarship, and received quite an ovation upon appearing upon the platform.

The fact that the physicians and surgeons on the staff of some of the leading metropolitan hospitals are unrepresented on the board of management, is continually leading to differences between the two bodies. At the Northwest London Hospital these differences have just culminated in the resignation of the whole medical staff, the reason alleged being the dismissal of one of the members by the Committee without sufficient explanation. It is satisfactory to learn, however, that the patients will not suffer by this sudden step, as each physician and surgeon has undertaken to continue his attendance on the cases at present under his care until they are well enough to be discharged. In the meantime it is just possible the dispute may be amicably arranged, an endeavor obviously to be desired.

With the special sanction of Her Majesty, the new building now being erected for the National Hospital for the Paralyzed and Epileptic, Queen street, is to be dedicated as a memorial to his Royal Highness, the late Duke of Albany. A meeting to receive a communication from the Queen on this subject has been held, the Earl of Shaftesbury in the chair. Of the cost of the memorial building, a balance of £12,500 remains to be obtained.

Mr. Edward Crookshank, who at the present time is Director of Convict Prisons in Egypt, has brought out a very useful antiseptic first dressing companion, for the use of soldiers in the field. A tin box, adapted to be worn in a pocket of the tunic, contains

a collapsible tube, to contain a cream of iodoform and eucalyptus oil, a skip of protective carbolized tow, and a carbolized gauze bandage; the whole weighs $6\frac{1}{2}$ ounces. Mr. Crookshank is, however, strongly in favor of salicylic silk or iodoform tow, as forming much more powerful antiseptic pads.

Dr. George Alfred Walker, known so well as "Graveyard" Walker, who died last week at his residence in North Wales, after a brief illness, was born at Nottingham in 1807. He became a licentiate of the Society of Apothecaries in 1829, and a member of the College of Surgeons in 1831. He studied for a long time at St. Bartholomew's Hospital, completing his professional education in Paris. Early in life he was deeply impressed by the terrible upturnings of human remains in graveyards, which he had seen in various parts of the country. For many years he resolutely waged a crusade against intra-mural interments, which ultimately brought about the passing of the law forbidding burials in church vaults, and which led to the construction of public cemeteries. In 1847 he gained possession of the notorious Enon Chapel, in London, from which he exhumed several thousand human bodies in various stages of decay, and had them entombed in a monster grave in Norwood Cemetery, at his own expense. He was the author of several works on sanitary reform and the graveyard question, and wrote a number of treatises on the skin, ulcers, gout, rheumatism, sciatica, and indigestion, which laid the foundation of a new era in the treatment of disease.

An excellent suggestion has been made with regard to the question of quarantine imposed upon vessels coming from infected ports. At present the same time is put upon all vessels alike. It is obvious that a steamer that has made a journey in three days is more dangerous than a sailing ship that left a fortnight previously. It is proposed that the length of quarantine should depend upon the date at which the vessel left an infected port.

The state of the River Thames below London is this summer in a very bad condition from a sanitary point. It is said to be due to the dry season, and also to the abstraction of great quantities of water above London by the various water companies.

An inquest was recently held upon the body of a man who having fallen from a barge, was stated by the medical witnesses to have died poisoned through swallowing a small quantity of the water. The authorities are now daily throwing upwards of a hundred tons of chloride of lime into the river at a cost of about nine pounds per ton.

Those who are interested in old, amusing records and anecdotes of the profession will find some interesting reading for leisure hours in "Mems., Maxims and Memoirs," by William Wadd, Esquire, L.T.R.S., Surgeon Extraordinary to the King, 1827.

The Medical Congress at Copenhagen is attended by more than 1,100 medical men from almost every country in the world. There were 110 from Great Britain present on the opening day, of whom 35 intend to deliver addresses. M. Pasteur has delivered an interesting address on morbid micro-organisms and vaccination. He described and explained his

late experiments of inoculation, and stated that no inoculated dog had yet died.

Sir Erasmus Wilson is dead. Of late years he has given a great part of his fortune away in charity. It was due to him that the Egyptian obelisk known as Cleopatra's Needle, which now stands on the Thames embankment, was brought to England. He founded the Chair of Dermatology in the College of Surgeons in 1869, and was elected the first professor. He published many works on diseases of the skin.

G. O. M.

COPENHAGEN, DENMARK, }
August 18, 1884. }

MR. EDITOR:—The eighth session of the International Medical Congress has held its meeting in Copenhagen, and the Congress has adjourned to meet again in Washington in 1887, the invitation of the American Association, tendered by Dr. John S. Billings, having been accepted. This meeting has been very successful in every way, being largely attended, especially by men from the Continent and the British Isles, together with a considerable delegation from America. Although no full directory has yet been published, it is probable that there are about 1,500 members present, and the city is crowded with them.

The exercises commenced Sunday, August 10, with an address by President Panum, in the presence of His Majesty, the King of Denmark, and in the evening with a dinner given by the President and the Executive Committee. They have continued through the week, closing Saturday, August 16. Each day, with the exception of Wednesday, the 13th, there have been two sessions of the Sections—the morning session being from 8 to 12 o'clock, and the afternoon session from 1 to 3 P. M.; and also there has been a general meeting from 3:30 to 5 P. M., at which addresses were given by Pasteur, of Paris; Crudeli, of Rome; Gull, of London; Virchow, of Berlin; and Panum, of Copenhagen. The Congress has been divided for work into fourteen sections, as follows: I, Anatomy; II, Physiology; III, Pathology; IV, Medicine; V, Surgery; VI, Obstetrics and Gynecology; VII, Ophthalmology; VIII, Pediatrics; IX, Dermatology and Syphilis; X, Nervous Diseases; XI, Laryngology; XII, Otology; XIII, State Medicine; and XIV, Military Medicine.

The official languages have been English, French, and German, and all of the exercises have been conducted in these languages, French being the most universal. It has frequently happened that a paper has been read perhaps in French, with the discussion opened in English, and continued in German.

The social element was not overlooked, and the whole city has been thrown open to its guests. Each day there has been some reception or dinner, chief among which were the dinner given by the city of Copenhagen on Thursday evening, and the reception and supper by the King and Queen on Friday evening.

Wednesday there were no sessions, and the members and their ladies were conveyed by fine steamers about twenty miles to Elsinore, where a fine lunch

was waiting their arrival in the old castle of Kronborg. In the evening they returned to Copenhagen by rail.

Although the chief business of a medical meeting is the dissemination and interchange of knowledge of a medical character, yet not the least benefit is the social element, the members learning to know each other personally, and ever after they appreciate each other better than if there is no acquaintance and they are known only at a distance. On this account I trust that the meeting in America in 1887 may be largely attended by the many distinguished men on this side of the Atlantic. N.

DOMESTIC CORRESPONDENCE.

TREATMENT OF CHOLERA.

BALTIMORE, Aug. 29, 1884.

DEAR DOCTOR:—While thanking you for publishing my note on Asiatic Cholera and the trouble you have taken to criticise it, I cannot refrain from drawing attention to certain facts that from haste seem to have been misunderstood. In the first place you say that "all these suggestions are founded on the assumption that the chief danger from cholera is in the loss of the water and salts of the blood, leaving that fluid too viscid to circulate." Now I wish it to be distinctly understood that I made *directly* no such assertion, but admit of course the importance of supplying liquid to help circulation, and think there are other circumstances that I am about to specify that are equally or more important. Prominent among these is a poisonous condition, leading to collapse in the last stages of cholera, typhus, yellow fever and Bright's disease, known under the name of uræmia. The substance *urea*, believed to cause this, is said to be found by chemical analysis in the serous discharges, vomit and tissues, and this it is, undecomposed, and as carbonate of ammonia, that helps to supply the food to *comma-bacteria*, or other low forms of vegetable life in the intestines, and as carbonate of ammonia, in company with carbonate of soda, gives the alkaline fluid, that I desire at first to dilute, and then get rid of at the expense of liquid injected into the peritonæum, bowels and areolar tissue rather than at that of the whole body. Another object I had in view but which I did not specify, and for which I intended to use the fountain apparatus *only* in the *areolar tissue* and *bowels* for fear of danger, was to decompose the *urea* in yellow fever, Bright's disease, cholera, severe typhus, etc., by injections of dilute liq., sodæ chlorinata, changing it into carbonic acid and nitrogen. A glance at the effect here produced shows how untenable the notion is that fluids injected into the peritonæum and areolar tissue will act the same as if injected directly into the blood-vessels, for if we should be foolish enough to do the latter, patients would probably perish from *nitrogen*, like air in the heart, and we all know, who have worked with the microscope, how water makes the red blood discs disappear, and acts on the zooids and æcoids, which probably accounts for its want of per-

manent good effect. Specific gravity, therefore, is an important consideration when fluids are to be thrown into the peritonæum, and it is to *this*, forced by your editorial, that I would draw *particular attention* and suggest that the liquid coming from the bowels and stomach, be tested by hydrometer at the bedside, and then an artificial fluid identical or slightly exceeding it in specific gravity if possible, be employed in the peritonæum to reverse the osmosis that you speak of, or prevent, by the liquids being of the same strength on both sides of the intestine, any current, either endosmotic or exosmotic.

As to the fountain which you think requires almost the stillness of death for successful application, I would simply say that I do not prefer it when it can be dispensed with, but think that a little patience on the part of the physician will enable him to adjust it by the long, soft, flexible, thin India rubber tubes in such a way, by rubber bandages, adhesive plaster or other substances placed around the limbs, as to make both fountain and tubes almost a part of the body, and allow the patient with the reservoir hanging around his neck, attached to the shoulders, on the upper part of the body, on pulleys slightly above the bed, or otherwise, as much movement as he desires. A simpler plan to get liquid into the tissues continuously, provided the patient were strong enough to bear it, would be to insert the hypodermic syringes without pistons or rubber tubes into the areolar tissue, and tie or bandage them in place, and then put the patient in a bath-tub filled with the artificial serum, using the tub as a reservoir. Finally (if all these suggestions should prove futile), my object was to gain time, so as to enable one to employ some more potent remedy, such as a gas or liquid in which low vegetable forms could not live, applied through the rectum or otherwise, putting the patient perhaps into a bath-tub full of dilute acid liquid sufficient to cover the body with the exception of the head, the rectum being kept open by a short tube, so as to continuously dilute by water pressure and act upon the walls and contents of the bowels, instead of using a syringe. Other germs or their excrements might also be used by the stomach and bowels to starve out the cause of the disease, as suggested in my article on Paraldehyde, and a desperate case that recovered after the use of weisbier, consisting largely of yeast, carbonic acid froth, and yeast plants in active fermentation, gives strength to the argument. You now see why I wrote so briefly in my former communication on this subject, for when we enter upon the treatment of cholera the road is rough, causing many bruises, and widens to such an extent as to become the despair of the traveler.

Very respectfully, your obedient servant,

J. R. UHLER, M.D.,

234 W. Fayette street.

SPINA BIFIDA.

On the 22d of April, 1884, I delivered Mrs. C. of a female child weighing 10½ lbs. The child was well-formed, symmetrical and very well nourished. At about the third dorsal vertebra a spina bifida pre-

sented itself about the size of a pullet's egg. The tumor was pear-shaped, and with a pedicle about an inch in diameter. The fundus was somewhat corrugated and purple. It appeared to contain a small quantity of fluid. There was a distinct opening in the vertebra at the attachment of the tumor, corresponding in size to an ordinary lead pencil. The child was very fretful and cried constantly and piteously when laid upon its back. It was much more comfortable when held upright than when in any other position. Any manipulation of the tumor caused the child to cry. When it was three weeks old I made a critical examination which thoroughly satisfied me that it was a spina bifida, that it communicated with the cord, and that it was increasing in size. I constricted the pedicle with a clamp to determine whether convulsions would occur. They did, but very moderate in degree. But this caused so much suffering to the baby that further interference was postponed until two days after, when it was decided to amputate it.

In the meantime the child worried and cried most all the time, and there were slight twitchings of all the extremities, but nothing occurred which amounted to a convulsion.

I transfixed the pedicle with a stout silk cord, tied it very tightly in two lateral halves, and cut it off. A small quantity of fluid (to all appearances spinal) escaped. The tumor collapsed, and on examination showed a serous lining. The child seemed easier as soon as it was removed; and though there was a good deal of disturbance in the nervous system, and a good deal of twitching of muscles all over the body for several days, there was nothing which amounted to a convulsion, and the child could now lie on its back and sleep. It was dressed antiseptically. On the fourth day the skin had given way under the ligature, which now contained only the "roots," if the expression is allowable, of the tumor. In four more days these came away, leaving only a healthy granulating surface, which in a few more days completely healed, leaving a cicatrix exactly like an ordinary umbilicus. The child is now (August 22) as strong and healthy as one could wish to see. A perfect cure had resulted in nine days.

To illustrate the wonderful power of nature to heal wounds, I may add that when this child was born, the mother's vulva was torn and lacerated beyond all recognition. The laceration extending down to the sphincter ani—down both sides of it, and up both sides through the labii. It looked as if the opening had been made by the explosion of a charge of powder. It was literally torn in shreds, one end of the sphincter vagina muscles protruded $\frac{3}{4}$ of an inch and could only with difficulty be replaced in position. Indeed, so extensive was the laceration that I deemed it unwise to sew it up lest I should get occlusion of the vagina. This state of affairs was brought about by the head *bursting* through a *perfectly unyielding* perinæum by a tremendous contraction of the uterus, and this notwithstanding I had my hand upon the head holding it back in order to avert such a calamity.

The parts were carefully cleansed and the woman placed upon her side with orders to remain so until

next day. When I examined her 24 hours after, I found the parts had so nearly approximated themselves as to leave very little, if any deformity, and as Dame Nature had made such a skilful beginning, I decided to leave the whole work to her, just to see what she was capable of doing. The result, the lady assures me, is perfect, a perfect recovery taking place in 10 days, and that she now "feels splendidly, better than she ever did before in her life," and certainly her looks and actions would confirm the statement.

F. W. EPLEY.

New Richmond, Wis., Aug. 22, 1884.

TÆNIA IN INFANCY.

DUBUQUE, IOWA, August 29, 1884.

EDITOR OF JOURNAL OF AMERICAN MEDICAL ASSOCIATION:

In your paper of the 23rd inst., Dr. J. R. Wilkins reports a case of tænia in a child 2½ years old. In my notes of Prof. Monti's lectures, held at the Vienna Poliklinik in the winter of 1878-79, I find mention of a case, said to have occurred in this country, where the infant was only 4 weeks old. To explain the occurrence of tænia at such an early age, it was supposed that the fœtus had swallowed a cysticercus floating in the liquor amnii.

Respectfully,

G. MINGES, M.D.

NECROLOGY.

We take pleasure in adding to the full biographical sketch of Dr. Woodward, given in our last number from the pen of Dr. Toner, the following just tribute received from the Surgeon-General's office.—Ed.

WAR DEPARTMENT, }

SURGEON-GENERAL'S OFFICE, }

WASHINGTON, D. C., August 20, 1884.

In announcing to the Officers of the Medical Department the death of Joseph Janvier Woodward, Surgeon and Brevet Lieutenant Colonel, U. S. Army, which occurred near Philadelphia, Pa., August 17, 1884, the Surgeon-General wishes to offer his tribute of respect to the memory of the deceased, whose distinguished career and valuable services, for a period of twenty-three years, have shed lustre on the Corps, and for whose untimely loss feelings of profound regret will be shared alike by his comrades in arms and by the profession at large.

Doctor Woodward was born in Philadelphia, Pa., October 30, 1833, and was educated at the Central High School of that city, graduating with honor as Bachelor of Arts in 1850, and receiving the degree of Master of Arts from the same institution in 1855.

He graduated in medicine at the University of Pennsylvania, April, 1853; entered the Army as Assistant Surgeon, August 5, 1861; became Captain and Assistant Surgeon, July 28, 1866; Major and Surgeon, June 26, 1876. "For faithful and meritorious services during the war" he received the brevets of Captain, Major, and Lieutenant Colonel U. S. Army.

He was assigned to duty in this office May 19, 1862, and from that date until the beginning of the illness which terminated in his death was intimately identified with its professional and scientific work.

While the valuable results of his life's labor are comprehended in a long list of miscellaneous publications, both professional and scientific, too familiar to the Corps to require individual mention, his greatest triumphs were won in the field of microscopical investigation in normal and pathological histology, and in his happy application of photomicrography to the purposes of science. In these pursuits he attained remarkable success, and achieved an enviable, world-wide reputation, leaving to science and medicine lessons of undoubted value and usefulness. Of his strictly professional work, the medical portion of the Medical and Surgical History of the War of the Rebellion was the crowning achievement. In the second part of this work he developed the results of his careful investigations into the nature and pathology of the intestinal diseases which had proved so fatal in the late war. Here, also, he displayed his wonderful capacity for that minute and exhaustive research which forms so striking a feature of his writings.

As in the case of his co-laborer, Otis, he yields to other hands the honor of completing his labors.

In addition to his engrossing professional duties, his restless activity of mind led him to seek recreation in his favorite studies—physics, art and philosophy.

Endowed with a retentive memory and of untiring industry, he acquired a vast store of information which he held available for use at will; fluent of speech, he took delight in the expression of his views and opinions, both in social converse and in the arena of scientific debate.

His fund of knowledge, his strong convictions, his tenacity of opinion and his quick perception, made him a controversialist of no low order.

With such a record, it is needless to speak of his zeal, his ambition or his devotion to his profession, and especially to the reputation of the corps of which he was so bright an ornament.

Of a sensitive, highly strung, nervous organization, the confinement, anxiety and labor to which he was subjected in his attendance upon the late President Garfield during his long illness, proved too much for a mind and body already overstrained by incessant labor, and precipitated the illness which finally terminated his life.

At the time of his death, Dr. Woodward was a member and ex-President of the American Medical Association, a member and ex-President of the Washington Philosophical Society, a member of the National Academy of Science, of the Association for the Advancement of Science, of the Academy of Natural Sciences of Philadelphia, and of the College of Physicians and Surgeons of Philadelphia. He was an honorary member of several American and foreign scientific, medical and microscopical societies, and the recipient of many distinguished honors from learned bodies in this country and abroad.

R. MURRAY,
Surgeon-General, U. S. Army.

MISCELLANEOUS.

ENCYCLOPÆDIA OF MEDICAL WIT, HUMOR AND CURIOSITIES OF MEDICINE.

The undersigned proposes to publish, during the coming year, a large volume under the above or a similar title.

In this undertaking he respectfully solicits the kindly aid of the profession. Witticisms, and anecdotes of a humorous, or curious nature are solicited. There are numberless unpublished experiences that would prove a source of amusement and instruction, and all physicians, druggists, dentists, and others supplying original contributions will receive due credit in the work.

Information regarding suitable literature—home and foreign, ancient and modern—will be gladly received, and highly appreciated. The author is especially anxious to avail himself of every source, and would highly appreciate all information concerning publications likely to be useful for reference.

All letters, contributions, clippings, books and other matter should be addressed to

JULIUS WISE, M.D.,
806 Olive street, St. Louis, Mo.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING* IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM AUG. 22, 1884, TO AUG. 28, 1884.

Head, John F., Colonel and Surgeon, granted leave of absence for four months. S. O. 201, A. G. O., Aug. 27, 1884.

Woodhull, A. A., Major and Surgeon, detailed as member of Med. Exam'g Board at U. S. Mil'y Academy, West Point, N. Y., vice Capt. R. H. White, relieved. Upon adjournment of the board to return to his proper station. S. O. 201, C. S. A. G. O.

Lippincott, Henry, Promoted Major and Surgeon to rank from August 17, 1884, vice Woodward, deceased.

Bartholf, J. H., Capt. and Ass't Surgeon, relieved from duty in Dept of the Columbia, and to report in person to commanding general Dept. of Texas, for assignment to duty. S. O., 199, A. G. O., August 25, 1884.

Finley, J. A., Capt. and Ass't Surgeon. The leave of absence granted him in S. O. 91, C. S., Dept. of Texas, extended two months. S. O. 196, A. G. O., Aug. 23, 1884.

Crampton, Louis W., Capt. and Ass't. Surgeon, to report at Creedmoor, L. I., N. Y., not later than August 30, as competitor; and, in addition thereto, as medical officer of the detachment of competitors. S. O., 41, Div. of the Atlantic, August 20, 1884.

Taylor, M. E., Capt. and Ass't. Surgeon, granted leave of absence for four months, to take effect on arrival of a medical officer at David's Island, N. Y., to replace him. S. O. 200, A. G. O., August 26, 1884.

Cochran, J. J., 1st Lieut. and Ass't. Surgeon, assigned to duty at the Presidio of San Francisco, Cal., S. O. 81, Div. of the Pacific, August 16, 1884.

Fisher, W. W. R., 1st Lieut. and Ass't. Surgeon. When relieved by Ass't. Surgeon Cochran, to report in person to Commanding General Dept. of Arizona for assignment to duty in that department. S. O. 81, C. S., Div. of the Pacific.

McCaw, Walter D., appointed Ass't. Surgeon with rank of 1st Lieut., to date from August 20, 1884.

THE FORMATION OF POISONS BY MICRO-ORGANISMS. CONSIDERED IN RELATION TO THE PRODUCTION OF DISEASE.

BY G. V. BLACK, M.D., D.D.S., JACKSONVILLE, ILL.

[Presented in Section of Practical Medicine and Materia Medica of the American Medical Association, May, 1884.]

INTRODUCTION.

If we review the history of the observation and experiment that has been had, bearing on the relations of micro-organisms to the production of disease, we may formulate the following propositions:

1. Experiment and observation has shown that there are many varieties of micro-organisms that do not produce disease or injury; that the mere presence of these life forms is not sufficient to cause disease.

2. Experiment has, also, shown that there are certain varieties of micro-organisms that do uniformly induce disease when they obtain entrance into the bodies of animals, or men.

3. All through the experimentation on this subject it has been noticed that poisons have appeared in connection with the disease producing organisms.

4. These poisons seem to be a product of the micro-organisms; and while produced only in connection with the life and growth of these microscopic plants, may be separated from them, and when so separated, induce direct poisoning similar to that induced by the poisons from the higher plants.

5. This poisoning is different from the disease induced by the growth of the micro-organisms in the body, in that it is direct, and immediate, while infectious disease arises only after a stage of incubation.

6. Therefore, it is probable that each infectious disease is induced by a specific micro-organism capable of developing in the blood or tissues, and forming a poison or poisons through the means of its vital energies; or physiological processes of digestion, nutrition, and the casting off of waste products.

These considerations suggest an extended examination of the physiological phenomena of life in its varied forms, as the best means of gaining a clear conception of the teaching of the facts developed by experiment. It will be seen by any one who reviews this whole subject closely, that, while the experimentation which has been had furnishes the strongest evi-

dence that disease results from the presence of micro-organisms—is brought about in some way through the life and activity of these lowly forms—the *modus operandi* by which they induce disease has been but partially explained.

Indeed, thus far, the principal effort has been to show that micro-organisms are regularly connected with certain processes of disease, and that these in no case occur without this accompaniment, rather than to show how they induce disease. This was necessary, in the beginning of this work, for the collection and collation of sufficient data upon which to construct theories and found a basis of truth, from which inquiry may proceed to the more perfect explanation of the mysteries of this important subject. The germ theory of disease as it stands to-day is essentially a mass of unexplained facts, developed by direct experiment of the most subtle nature; so subtle, indeed, that there are but few men who have the natural endowments and rigid training necessary to verify them in a manner, and with the certainty that the thought of the time demands. Under these circumstances, and with the plain fact before us, that the mere presence of the organisms is not a sufficient cause of the diseases which experiment teaches us are induced by them, we naturally turn to the well-demonstrated fact that micro-organisms do give rise to *poisons*, for an explanation of these phenomena.

It is our purpose now to make an effort to trace the phenomena presented by the life force in its relations to matter, with the end in view of elucidating this difficult point. In this direction, as it seems to me, we are most likely to find a satisfactory answer to some of the teachings of experiment that have appeared difficult to understand. In a brief paper like this, however, we can only glance at the principal points necessarily involved in a complete discussion of the subject.

The phenomena that we will now review will be digestion, absorption, nutrition, and the formation of waste products in the several forms of life, after which we will study briefly the relations which the changed forms of matter induced by the physiological activity of micro-organisms holds to the production of disease. This is necessarily a biological study.

Digestion is a process of solution and chemical reorganization of food material by which it is fitted for reception by the life force. The material thus prepared is conveyed within the organism by absorption or osmosis. Digestion and absorption are the admitted forerunners of all nutritive processes; the initial steps by which nutrition is rendered possible. I

hold that this is true in all the varied forms in which the life force is manifest. That there may be substances that are made use of by the life force without previous digestion is perhaps true; but there is, perhaps, no living thing not provided with the means of this mode of food preparation.

For the lack of time in which to present this entire subject, I will only present a synopsis of the parts relating to digestion and absorption. All digestion is performed by soluble ferments, elaborated by the organism, whether this digestion be performed in an alimentary canal or elsewhere.

A soluble ferment is a substance or body elaborated by the organism, for the purpose of dissolving and rearranging the chemical forms of food material, fitting it for reception by the organism.

The formation of a stomach or alimentary canal is an arrangement for the conservation of force, but in no wise changes the *modus operandi* of the digestive function. The digestive body may be thrown out into the surrounding media where digestible material is suspended, or upon digestible solids, and perform its function without the aid of a stomach. In this way the yeast plant digests cane sugar. In this way the micrococcus ureæ digests its food. In this way the bacterium termo has been shown to be able to digest starch.

It has been proven that the pathogenic micro-organisms are capable of digesting their food, and rendering it fit for being taken up by osmosis, by growing them on solid media which could not be appropriated without such preparation.

The embryo of the seed digests the store of starch laid up for its nutrition, by eliminating a digestive body called diastase, and by this means prepares its food material for assimilation, until such a time as it shall have developed the organs by which it gathers its own food. The same is true of the embryo in the egg.

The higher plants take up substances that exist in an insoluble condition in the ground in which they grow, by means of an excretion by their roots, which performs their solution, rendering them capable of being drawn in by absorption or osmotic action. This is a form of digestion.

The tissues of the higher animals are capable of forming digestive bodies under certain peculiar circumstances; e. g. the digestion and removal of the roots of the temporary teeth at the time of shedding; the removal of bone during changes of form; the formation of sequestra in case of death of a portion of bone.

The tissues of the higher animals are also capable of forming a menstruum for the digestion and removal of substances accidentally, or purposely, lodged in the flesh. This is seen in the digestion and removal of the sponge, in the sponge graft; in the digestion and removal of the catgut ligature; in the invasion and partial removal of the sequestra of dead bone, and of pieces of ivory driven into the flesh.

In short, everything endowed with life, is, also, endowed with the power of preparing the food material necessary for the support of that life.

WASTE PRODUCTS.

In the beginning of the germ theory controversy, Schwan seems to have recognized that carbonic acid and alcohol were the excrementitious products of the yeast plant (*Annalen der Pharmacie*, Band 29, S. 93 und 100), Liebig in opposing the theory, alludes to this and recognizes that such a conclusion would necessarily follow, if fermentation were proven to be the result of the life force. (*Agricultural Chemistry*, page 124). Since that time, however, this idea seems to have been lost sight of by writers on this subject. Sometimes we see indefinite allusions to it. But there is no definite expression of the general law, that all forms of life must have their specific waste products, as they are seen in the animal forms. The remolecularization¹ of matter is continuous with the duration of life. The life force is dependent upon the remolecularization of matter for its support. No manifestation of the life force, in any form whatever, can be conceived of without this accompaniment. As the steam engine is dependent upon fire for its power, so is the life force dependent upon molecular changes in matter for its continuous existence. We can have no conception of life in the material form without the accompaniment of these changes. All forms of life are continually taking into themselves fresh increment of matter, in some form. This fresh increment of matter is converted into other molecular forms, for the support of the energies of that life which performed this conversion; and when this is accomplished it must give way to fresh increments of matter, which in turn undergo similar remolecularizations. The old must give place to the new. There is no such thing as standing still, except with definite provisions for temporary inactivity. Otherwise than this, inactivity is death. As new material is added, the old must be disposed of; must be cast out, or built up into formed material; where it takes no farther part in the physiological activity of the organism. Continuous molecular change of matter (inmolecularization) is the law of physiological existence.

As the living form must be supported by fresh increment, so it must give back excrement. Life is not to be supported by the continuous remolecularization of the same matter. After it has once accomplished its function in the economy, it becomes unfitted for further use, and is disposed of in one of two ways. It is either built into formed material or it is cast out as excrement. In either case it is dissociated with the physiological activity of the organism. The sum of the excrement, and formed, or fixed material, must in all cases equal the sum of the increment. There is nothing lost, nothing gained. All increment not present in the organism, must have been given back to the outside world as excrement, no matter what the form of life.

There is a general law observed in the formation of the excrementitious matters. Liebig while opposing the life theory of the fermentations, gives expression to this, as a law of all fermentations. I translate from "*Chemische Briefe*, 6te Auflage, S. 358":

¹The word remolecularization is used to express the fact that a molecular change has occurred in matter, without expressing the character of that change.

"Fermentation is always in its results, a splitting of combined atoms into a compound rich in oxygen, and a compound poor in oxygen; so in alcoholic fermentation a certain amount of oxygen is divided from the sugar in the form of carbonic acid, and we obtain the inflammable alcohol poor in oxygen." When we compare this statement with the facts now known, we find it correct. But we may do more than this; for if we compare this statement with what is now known of animal and vegetable life, we find that it holds good here also. For in the animal forms we have as excrementitious products, the same carbonic acid rich in oxygen, and urea poor in oxygen. Here we see, as a final result of the remolecularizations, excretory products analogous to those of the yeast plant. I have already shown that, in the physiological sense, there is a close resemblance, a certain oneness of plan, existing among all forms of life in the matter of taking food. Now it is my purpose to show that this identity of plan is extended to all the living forms, in the matter of waste product as well. While there are almost unending differences of outward conformation, there is a continuous physiological sameness in them all. While certain cells, endowed with the power of combination for the building up of wonderful forms, as in the man, or in the tiger, in the lofty palm, or the forest oak; others not possessing the power of organization into complex forms, fall apart and carry on their physiological processes simply, as in the yeast plant, or the mycoderma aceti.

In the unicellular organisms, all the vital functions so far as they are differentiated, are carried on in the single cell, and in the higher animals, which proceed from the growth and development of some single, and equally minute germ, specialization of function goes hand in hand with specialization of physical form. Yet in all this specialization, there is no radical change in the functions of the individual cells, nor is the sum total of the physiological phenomena modified in their nature.

In most cases, apparent new functions, seen as we ascend the scale of life, consist, when closely examined, of vicarious cell action. Not a new function, but a particular function performed for the community of cells, so to speak, by certain cells specialized for that purpose, as we have already seen in the consideration of digestion.

Waste products may be divided into two classes: the respiratory and the urinary. The respiratory product is always rich in oxygen, while the urinary product is always, comparatively, poor in oxygen. This distinguishing feature remains constant for all forms of life, whether animal, vegetable, or the lower forms, that are so doubtful that some have thought it well to create for them a separate department.

The waste products of the animal forms are sufficiently known. The consideration of them has been entered into by every author who has written on the subject of physiology. Therefore a consideration of them here is not necessary. All of the excrementitious products possess toxic, or poisonous properties in some degree. If, by the occurrence of accident,

or disease, urea be retained in the blood of an animal, it soon presents symptoms of toxæmia, and if the accumulated urea is not speedily eliminated, the animal dies. This is a general law of the waste products. No living being can sustain life with a large percentage of its waste product retained in its circulation. Neither can a micro-organism continue to grow after a certain amount of its waste products have accumulated in the menstruum in which it is placed. Urea may be regarded as the alkaloid of the animal kingdom, and is the analogue of the alkaloids of the vegetable kingdom.

The consideration of the waste products of the vegetable kingdom is especially difficult for several reasons: Plants are characterized by the large amount of their formed material, as compared with the food material consumed by them in their processes of vital activity, and therefore, the amount of their waste products actually excreted is proportionally small. In them, however, other means are found for freeing their circulating fluids of waste materials, than that of actual excretion as seen in the animal forms, which will be considered further on. There is, however, a sufficiently copious excretion of the respiratory waste product, carbonic acid, in plants, and in addition to this, oxygen. These are too well known to require further comment here.

There is also a true excretory function performed by the roots of plants, and by seeds in the process of germination. When barley or other grain is caused to germinate in pure chalk, acetate of lime is uniformly found to be mixed with it, after the germination is somewhat advanced. * * * In this case the acetic acid must have been given off (excreted) by the young roots during the process of the germination of the seed." (Vide Johnston's *Agricultural Chemistry*, page 81).

This well authenticated fact may be regarded as the foundation of the theory that plants are endowed with the power of excretion. It is supported by the authority of Decandolle, and the convincing experiments of Macaire, although the experiments of others have shown that this excretion is limited to very small amounts of matter. Macaire seems to have found opium in the soil in which poppy plants grew. He also found, on washing with pure water the soil in which these plants grew, that it yielded a considerable quantity of acetic acid, and a trace of a brown organic matter.

Liebig devotes considerable space to this in his *agricultural chemistry*, with special reference to the possible effects of these excrementitious substances on the rotation of crops. Other chemists have also occupied themselves with it; and while it has been definitely shown that in some special cases plants may eliminate a sufficient quantity of excrementitious matter to prove injurious to successive generations growing on the same soil, the rule is that poisoning from this cause is not to be expected. Enough has been demonstrated, however, to show conclusively that many of the substances formed in the fermentations are also excreted, in very small amounts, by various plants. Even alcohol and ammonia are formed in this way, in small quantity. Although these sub-

stances, as a rule, contain no nitrogen, their chemical construction is such as to show their relationship to urea, and leave no doubt that they are properly analogues of that product in the animal kingdom.

ALKALOIDS.

By far the most important compounds to be considered in this connection are the alkaloids. These bear the same relation to plants that urea bears to the animal forms. There is seen in their chemical conformation, and characteristic properties, a marked relationship; and yet among them is found a wide divergence of poisonous effects. All possess in some degree the power of intoxication, while a few are the most virulent poisons known. Nearly all are composed, as urea, of carbon, hydrogen, nitrogen and oxygen. In a few of them oxygen is lacking, and in all the nitrogen is in smaller proportion than in urea. As we descend the scale, the nitrogen disappears, the oxygen is increased, and we have the organic acids and alcohols. All of these are waste products of the vegetable kingdom, though they are not all excreted.

As we have already seen, the higher plants are marked by the apparently small amount of their waste products and the large amount of their formed material. The formed material presents two very marked characteristics, which will perhaps, be better understood if we designate them as formed material, and as fixed material. The formed material is elaborated and stored away for future use, such as the starch, oil, etc., surrounding the germ in the seeds, and in certain organs of the plant, and various other products designed for future employment by the vital energies of the organism. The "fixed" materials, on the other hand, are such as are placed permanently beyond the vital energies of the organism. Some portions of the fixed material may still be of use to the plant by the physical support it gives to its organs; as lignin, which forms the stems and branches of trees, and the bark which serves them as a protection. They are not, however, of any further physiological use to the plant after having once, or a few times, served as conduits for the circulating fluids. Although waste products may be found in the fluids, as in the blood of the animal, it is in the fixed material that we find the bulk of the waste products of the plants, and it is here that the toxic principles are found in greatest abundance. Instead of being excreted, thrown out to the outer world, they are stored in the disused cells of the wood, and bark, united with other waste products in the form of insoluble compounds. This fact seems to have prevented an early recognition of their real nature.

Sachs, in his text-book of botany, describes them as "degradation products, which are no longer useful to the plant," and as, "secondary products of metastasis." When we look over the products thus set apart by Sachs, we find that nearly all of them may be set down at once, as analogues of the urine in the animals, of the alcohol, the acetic acid, the butyric acid, etc., of the fermentations.

It is to these products that we look for the most of the vegetable substances now employed as medicines.

The active principles of these are the alkaloids. Therefore their effects upon the animal economy are well known to medical students, and need not be recited here. There are many other substances found in this relationship to the vital energies of the plant, which are worthy of special consideration if we had the time at our disposal. Tannic acid is one of the most constant of these products, and there are a large number of others not yet mentioned. We will only mention one other class of substances, the coloring matters which remain in the wood cells in a fixed condition, as a result of secondary metastasis. Precisely similar phenomena are seen in the micrococcus chromogenes, of which there are several varieties known. All such circumstances serve to point us forward in our efforts to explain the mysteries of nature.

BACTERIA.

When we come to consider the waste products of the bacteria and the allied forms of life, we are at once amazed and astounded at the wonderful power they possess in the remoleculization of matter. This is one of their special characteristics. This seems to be the form of life in which the largest amount of food material is consumed and the largest amount of waste product given back, with the least building of tissue. The largest amount of remoleculization, with the least amount of formed or fixed material. A whole jar of milk is turned sour, every particle of its sugar of milk converted into acid, and yet the amount of the formed material is so insignificant that it requires an acute and trained observer, provided with the best means of search, to find a trace of it. When a small amount of yeast is added to a solution of sugar, the whole of the sugar will be remoleculized, producing carbonic acid and alcohol within a few hours. Then we may take the example of the destruction of the dead carcass. The history of the experimentation of the past shows conclusively that it does not decompose if protected from these low organisms. Yet within a few days it is swarming with this form of life, in the presence of which it melts away like ice before a summer sun. It is first attacked by one form, which consumes, and throws out its waste products, as long as it can work in the continually increasing quantity of its own effete matter. Then it must give way to others that have already appeared on the scene of action, to which the waste products of the first are no hindrance. These in turn, give way very soon to still other forms, which again remoleculize the waste products of all the former that may retain a semi-solid or a liquid form, with any residue of the original carcass that may still remain; and, in an almost incredibly short time, the whole carcass has disappeared. The labors of Pasteur have thrown much light upon this subject. The fact that the acetic acid plant will again remoleculize the waste product of the vinous yeast plant, alcohol; and after that the mucidines will still remoleculize the acetic acid, converting it in turn into still other compounds, is full of instruction for all these processes. It would seem that the vegetable world is divided into two great classes of life forms, and that it is the office of the one to build up, and the office of the other to

tear down. Of all the life forms, the higher plants have the greatest power of structure building, both as regards quantity, in comparison with the amount of material consumed, and as to the actual quantity of structure formed; while in the lower plants, the bacteria and their allied forms, exactly the opposite of this is found in every particular.

No other form of life consumes so much in comparison to the amount of structure built. They are emphatically the destroyers of organic forms, physiologically constructed to, and for this end.

They must digest their food. If it be solid or semi-solid it must be liquefied in order to be absorbed. Then it must enter into the cells by the process of osmosis, and under the influence of the life force, be converted into protoplasm—albuminoids—into the tissues of the growing plants. After this come the waste products. How? The cell dies? No. This will not explain the phenomenon. If it were the death of the cells we would find the chemical forms of the cells in the waste products. This is not the case. Death does not alter the chemical forms. Therefore, there is remoleculization for the formation of the waste products. A vital process of shedding out the used material. The life force letting go of the matter it has in its grasp, and casting it out, as no longer of use to it.

It is by a vital process, then, that the waste products are separated from the living organisms, and in the bacteria, the general laws of physiology remain unchanged. Here, as elsewhere, we find the definite respiratory product, and the toxic, or urinary product. A sufficient number of these have now been studied enough for us to gain some notion of them, yet our knowledge is still limited to a few forms, among the bacteria and their allies. The best known is the yeast plant. In this we have alcohol, succinic acid and glycerine, as the urinary excrement. The bacterium lactis produces lactic acid. The mycoderma aceti produces acetic acid. Another form produces butyric acid, another a kind of mucus, another ammonia; while others still produce as their waste products, all of the ill smelling products of putrefaction.

I append a table of those best known, in connection with a table of the waste products of other forms of life, for comparison.

TABULATED STATEMENT OF THE WASTE PRODUCTS OF VARIOUS ORGANISMS.

Respiratory Products.

Toxic Products.

ANIMALS.

		Sulphhydric acidHS
		Fat acids (various eqv.)CHO

There is, perhaps, no other one set of organic compounds that have puzzled chemists more than those given in this table, or that have been, and still continue to be, of more interest in the scientific world. The table as it stands is only intended to give an outline view of these organic matters as a class, by setting before the reader fairly chosen specimens from the different forms of life. It is not intended to be in anywise exhaustive, but simply a comparison of these products. The similarity of their chemical construction will be apparent at a glance; and yet they differ greatly in their toxic properties. Some, as strychnine, are violent poisons to the animal kingdom. The members of the acid series vary from the alkaloids in that they contain no nitrogen, and they also vary as markedly in their toxic properties. Their close similarity to the alcohols will be noticed. It will also be noticed that some of the waste products of the higher plants are the same as those of the lower organisms.

There is, perhaps, an important difference to be observed here. The alkaloids of the higher plants, from the nature of their mode of excretion, are thrown out of physiological activity by being combined with the vegetable acids in the form of insoluble salts, and thus laid away in the "fixed material" of the plant. On the other hand, the animal alkaloids, urea, uric acid, etc., are eliminated in a soluble condition. In case of the micro-organisms, the waste products are very generally eliminated in a

soluble condition, also. But the comparatively more abundant product in the lower forms, is of much importance in this connection. Those given, are from the few that have been best studied.

In these no proper alkaloids have thus far been made out by isolation and exact analysis, but we cannot argue from this circumstance, that none of the lower organisms produce true alkaloids. As yet, but very few of them have been accurately studied, and these have, for the most part, been those that have been found useful, rather than poisonous.

On the other hand, we have much reason to believe that true alkaloids, of a poisonous nature, will be isolated at no distant day. We have already abundant evidence that poisonous properties are developed by a number of these forms. Otherwise how can we account for the results of the *bacillus anthrax*. How else can we account for sepsis, on the germ theory; except to suppose that a poisonous alkaloid is one of the products of the organism? How else can we explain Dr. Koch's results in the production of gangrene in mice, but to suppose that some product of the remoleculization by the organisms spread among and destroyed the tissues wherever they went. Again in the matter of sepsis, already referred to, it has been abundantly shown that the fluids contaminated by the bacteria are poisonous, when separated from the organisms; thus proving again that there is an organic poison developed which is fully capable of producing its effects in the absence of the life that produced it, the same as is seen in the alkaloids from the higher plants. This has taken the name of sepsin, after the order of the naming of the vegetable poisons; although it has not as yet been properly isolated and examined.

Many instances of a like nature might be brought forward if time would permit; but it is no part of my intention to treat this subject exhaustively. Some of the cases seem to show that the poison is of the nature of a local irritant only; as appears in Dr. Koch's demonstration of the *bacillus tuberculosis*; while many others seem to be general poisons with special tendencies to particular organs, as is seen in the splenic fever, produced by the *bacillus anthrax*. This is sufficient to show that there is much yet to be learned in this direction; indeed that this work is, as yet, in its infancy. In truth, the work done thus far has been in the nature of proving that organisms are regularly connected with the fermentations and decompositions, and, also, with certain processes of disease; rather than any effort to show how they bring about these results. This was necessary in the first instance, as the fore-runner of a farther, and more complete understanding of the subject that must come from a closer study of the modes through which these low organisms produce their effects. It is plain that we cannot know any one of the disease germs until all of the products of its remoleculizations have been isolated and studied, separate, and apart, from the organism itself, as has been done with the products of so many of the higher animals and plants. I see no other plan by which we can ever know the capabilities, and all of the possibilities, of micro-organisms in connection with the production of dis-

ease. In most cases of the discovery of poisonous properties in the higher plants, the specific product of the plant in which the poison resides has proven itself capable of isolation by the means known to chemists; and the disease producing poisons of the lower organisms will do the same when the effort to find them has been prosecuted with sufficient skill and energy. As alcohol has been isolated, as the vegetable alkaloids have been isolated, as the toxic elements of the waste products of animal life have been isolated, and as, through this isolation, the exact properties of these agents have become known to us, so must sepsin be isolated, so must the poisonous product of the *bacillus anthrax* (*Anthraxine*) be isolated, so must the poisonous principle of every disease producing germ be isolated, and each of these studied separate, and apart, from the organisms which produce them; and in each case their properties must be demonstrated and determined by direct experiment, before they can be said to have been accurately studied, and that we know their properties and capabilities. This is the recognized means of learning the powers and capabilities of the higher plants and animals. No one is foolish enough to deny the value, the necessity, of the knowledge to be gained by this mode of study in the vegetable kingdom. If there has been any truth arrived at in all the research that has been given to the subject of the production of disease by the lower organisms, that truth requires to be extended, and rendered more exact, by the modes of study we have just indicated.

MANNER OF ACTION.

I may be permitted to make a suggestion in regard to the cause of the difference that is so often noticed in the comparative liability of different persons to attacks by these organisms. Several persons receive wounds. So far as can be seen, their chances for a speedy recovery are equally good; but some of these develop sepsis, while others do not. Now much of this is explained by the fact that we are unable to perceive the entrance of these organisms, and they may gain admission to the one and not to the other, and we be none the wiser until we find that sepsis is established. Yet over and above all this, there is a certain residue of cases that show that different persons are liable in different degrees, to sepsis, and the class of patients to which it refers, have been pretty closely defined. They are those whose powers of life have been weakened, by whatever cause. This is said to be the resistance of the tissues to the invasion of the organisms. How do they resist? Now if we accept the explanation of the formation of the digestive bodies, as previously explained, this supposition becomes tenable. When an organism, or spore of an organism, falls upon a cell, or naked granulation of a wound, and finds there the conditions suitable for its development, its digestive body is at once thrown out, for the preparation of its food material which exists in the tissues with which it is surrounded. This digestive substance proves irritant to the cell upon which the germ has fallen. This irritation excites the cell to throw out its peculiar digestive body for the removal of the irritant with which it is beset. Here we get a glimpse of the

antagonists. It is cell against cell; digestive body against digestive body. A contest has begun.

Which will win? The stronger, of course. If the man be vigorous, and resistant, and his tissues highly endowed with the energies of life, the chances are this much in his favor; but if, on the other hand, his powers of life be at a low ebb, if his tissues respond to irritants but feebly, then the chances are thus far in the favor of the intruding organism. In the first case, the cell upon which the intruding germ has fallen, responds promptly to the irritation; a substance calculated to free it from the effects of the intruder is formed, and poured out upon it, and meets the digestive body of the intruder, hindering, dissipating, and nullifying its action. In this way the intruding germ is in many cases, possibly, overcome and driven out or destroyed. In the opposite case, where the vital powers are at a low ebb, the response to the irritation is perhaps very sluggish, the digestive body is poor in quality, and scanty in quantity, and the intruding germ has an easy victory.

If we suppose that the intruder is a spore, a seed with a store of food material laid up within its shell, the case is not different essentially. The history of the experimentation on this subject shows that during this process excretory products are thrown off, and these may prove direct irritants that will arouse the resistant energies of the tissues.

Surely if the tissues are capable of forming, by reason of irritation, a secretion that will digest a piece of ivory that has been thrust into the flesh, which has been proven by direct experiment, we should expect this kind of resistance to be offered to the development of disease producing germs.

Again, the history of cases shows that sepsis is most liable to occur in the early time of the healing of wounds, at a time when the tissues may be supposed to be still suffering from the effects of the shock. In this case it must be supposed that the tissues are not so well able to contend with the intruding germs as they are afterwards, when the process of granulation is going forward vigorously.

We have also experimental evidence establishing this point. Sonnenschein found that certain bacteria with which he was experimenting failed to grow in the tissues of an animal. Believing from the results of previous experimentations, that sepsin injected with the bacteria favored their development, and having found the effects of sepsin similar to that of sulphate of atropia, he injected a small amount of that drug with the organisms, and found that under these conditions they grew and produced sepsis. It is difficult to see how the sulphate of atropia could aid the bacteria otherwise than by paralyzing the tissues temporarily, preventing their resistance until the organisms had established themselves. A number of other experiments have developed facts of a similar nature.

Gradle says, page 123: "We do not know whether putrefactive bacteria exert any direct influence upon the exposed tissue. Even if that be not the case, the products of decomposition which they engender irritate the wound in an unmistakable manner. This is seen in the redness and sensitiveness of the margins

of the wounds. *These bacteria are always overcome by the tissues.*"

Observations have been recorded by a number of competent observers that go to show that the white corpuscles of the blood, the leucocytes and the wandering cells exert a special influence against the intrusion of micro-organisms. These cells appear to pick up the organisms and take them into their interior, and I am of the opinion that in very many cases the organisms are destroyed—digested—by these cells, but in other cases the cells are overcome—digested—by the organisms. It becomes a question of the relative power of the opposing digestive bodies.

CONCLUSIONS.

In conclusion, allow me to sum up in several definite propositions, in order that the discussion may be the better directed, and confined, to the more important points brought forward.

1. All cognizable forms of life are dependent on the production of molecular change in matter for their continued existence.

2. Every cognizable form of life, capable of independent existence, must have the power of digestion for the preparation of food material for the nutrition of its material structure.

3. Each living cell must appropriate to its nutrition food material prepared by a digestive body of its own formation, or by the appropriation of material prepared for it vicariously by some allied living cell.

4. Every living cell must support its life and material structure by the continued imbibition, and remoleculization of matter within itself; except during the special provisions of rest, as in the seed, egg, etc.

5. Every living cell must, as the result of the remoleculization of matter within itself, form waste products of two classes; a respiratory waste product rich in oxygen, and an urinary waste product poor in oxygen. All waste products are poisonous to the form of life from which they emanate.

6. Natural organic poisons are uniformly waste products of the organisms in which they are formed.

7. Pathogenic micro-organisms, by their remoleculizations of matter, form poisons of the nature of the alkaloids, which are the active agents in the production of disease.

8. While I should not class the digestive bodies, and diastases, as organic poisons, they may act as irritants when applied to another form of life than that which produced them.

9. The normal tissues of the animal resist the invasions of micro-organisms by throwing out, or forming a digestive body calculated to destroy them or dissipate and nullify their action; aroused thereto by the presence of, or the irritating agents given out by, the organisms.

A YEAR'S SURGERY AT THE LONDON TEMPERANCE HOSPITAL.

BY A. PEARCE GOULD, F.R.C.S., M.S.

Surgeon to the London Temperance Hospital; Assistant Surgeon to Middlesex Hospital, London; Surgeon to the Royal Hospital for Diseases of the Chest, London.

Read in the Section of Surgery and Anatomy of American Medical Association, May, 1884.

When in July of last year I had the pleasure of taking the distinguished President of the American Medical Association, and Professor Dennis, over the wards of the London Temperance Hospital, Dr. Flint extorted from me a promise to send a short paper to the Washington meeting of the American Medical Association, containing some account of my surgical experience at that hospital. It is therefore in redemption of that pledge that I venture to lay this brief communication before this distinguished audience.

In 1873 a house was taken in Gower street, London, and converted into a hospital for "the medical and surgical treatment of the sick, without the ordinary administration of alcoholic compounds;" and in 1882 the institution was removed to its present well-found and commodious building in the Hampstead Road. At first only 52 beds were opened, but at the present time, building operations are being carried on, and before the close of the year it is hoped that a hospital of over 120 beds will be in full working order.

In the autumn of 1882 I was asked by the Board of Management to undertake the charge of the surgical patients, and I entered on my duties on Jan. 1, 1883. I propose to lay before you a few facts derived from my experience since then, and will base them upon all the cases admitted under my care during the year 1883.

I must, however, make one or two preliminary observations to explain the nature and the mode of the work done at this hospital.

1. The patients are not all teetotallers; all the necessitous sick are alike admissible to the wards; and personally I may say that the fact of being an abstainer or the reverse never influences me in recommending a patient for admission. Practically a large number of abstainers seek admission, and I find that among my patients during last year they amounted to 74, or 39 per centum.

2. No selection of patients is made except such as is employed in every hospital, that is incurable cases and cases of infectious disease are the only ones inadmissible.

3. Alcohol is not given as an article of diet under any form or under any pretext; nor is it used in the preparation of tinctures, infusions, or other medicinal compounds.

4. The visiting staff are free to administer alcohol in any form and in any amount to any patient under

their charge, when they deem fit. The only restriction being that in such cases careful notes should be made of the condition of the patient before the alcohol is given, the amount of alcohol taken, and the effects observed.

I am anxious that it should be clearly understood that alcohol is not excluded from the hospital altogether, but only as an article of diet and as a vehicle for other drugs.

In the early days of an hospital, and especially such an one as the London Temperance Hospital, it is not possible to keep the surgical wards full of acute or severe cases. But during the year 1883 I find that there were 190 cases admitted under my care. Of this total 9, or just 4.73 per cent. died.

I cannot, in the time allotted to me, give details of the individual cases, and I propose, therefore, to attempt only a brief classification of them, and to add a table of operations; details of the fatal cases, and then, finally, make some remarks upon the value of alcohol in surgical practice.

There were in all sixty-seven (67) cases of injury admitted into the hospital. Among these were five (5) cases of compound fracture, fifteen (15) cases of simple fracture, two (2) dislocations, sixteen (16) wounds, including wounds of scalp and a wound of the temporal artery with severe hæmorrhage; twelve (12) contusions, five burns and scalds. Of these 67 cases four died.

The cases of disease amounted to a hundred and twenty-three (123) with five (5) deaths. These included thirteen (13) cases of disease of the joints, fourteen (14) cases of disease of bones, twenty (20) cases of disease of the alimentary canal, twenty (20) cases of disease of the genito-urinary system, sixteen (16) cases of abscess, eleven (11) cases of ulcer, nine (9) cases of tumor, and twenty (20) cases that may be grouped as miscellaneous.

In one of these cases, to be mentioned directly, alcohol was given, but not in any of the remainder.

In addition to minor and trivial operations there were forty (40) operations performed which may be here detailed:

Amputation of thigh,	1
do of leg,	2
Colotomy,	1
Gastrotomy,	1
Castration,	2
Removal of tumors,	5
Rapid lithotripsy,	1
Radical cure of hernia,	1
Excision of varicocele,	1
For hæmorrhoids and prolapsus ani by clamp and cautery,	10
Opening knee-joint,	3
For epithelioma of lip,	2
Excision of tongue and submental glands,	1
For genu valgum (MacEwen's operation),	2
Excision of tarsus,	1
External urethrotomy,	1
For fistula in ano,	3
For necrosis,	2

It is only needful to add particulars of some of these cases. The amputation of the thigh was for advanced central sarcoma of the lower end of the femur. The patient, a lad aged 18, was up ten days after the operation, and left the hospital on the 22d day quite well. The first case of amputation of the leg was in a man 66 years of age, admitted with a compound fracture of tibia and fibula, for which secondary amputation through the upper third of the leg was performed. There was a little necrosis of the tibia, and a troublesome abscess and neuralgia in the stump, and the man was in the hospital 115 days after the amputation. The remaining amputation was at the same site for incurable ulcer of the leg in a woman, aged 55. The stump healed up without complication. The cases of colotomy and gastrotomy are elsewhere referred to. The patient upon whom rapid lithotrity was performed was 32 years of age, with a small stone. The knee-joint was opened in one case for the removal of a loose cartilage, with complete success. In another patient both knees were opened for very long standing hydrops articuli. The joints when apparently nearly healed suppurated, and the girl got into a hectic condition, and was removed from the hospital by her friends. I have since heard that she has recovered. In a third case I opened the knee-joint and removed the whole of the greatly thickened synovial membrane. This patient died. The only other operation of gravity was a removal of the tongue behind the circumvallate papillæ, by the scissors, and excision of infiltrated submental and submaxillary glands for advanced epitheliomatous disease. This patient, æt. 66, recovered well, left the hospital 35 days after the operation, but has since died from recurrence in the cervical glands.

The fatal cases were nine in number:

1. The first was the case of a laborer, 41 years of age, admitted with strumous synovitis of the left knee-joint, of four months' duration. He was a tall, thin, pallid, delicate-looking man. For two months he was treated with rest, extension, counter-irritation, and the usual remedies, but his local and general condition becoming worse, I was compelled to resort to operation. The man absolutely refused amputation, and I accordingly performed antiseptic erosion, making a free incision into the joint on each side, and removing the thickened synovial membrane. This was not followed by any effort at repair, but there was profuse suppuration, the discharge was scant, but the temperature ranged high, and he gradually sank and died from exhaustion. At the autopsy an old cavity was found at the apex of the left lung, miliary tubercle in the right lung, amyloid degeneration of the liver and kidneys; the articular cartilage of the knee-joint was all eroded.

His appetite continued good until a week before death.

2. The second case was that of a woman, aged 62, admitted with intestinal obstruction of fourteen days' duration. There had been vomiting three and again two days before admission, which was stated to be fecal. But it was not until four days after admission that she vomited again, when she brought up several pints of liquid fecal matter. Accordingly, as I had

administered copious enemata repeatedly without avail, on May 26 I opened the colon in the right flank, and liberated at once about two pints of liquid fecal matter. The woman, however, died next morning from collapse. At the autopsy a cancerous stricture of the middle of the transverse colon was found. The intestines were somewhat congested, but there was no lymph on them, or loss of polish anywhere, nor any evidence of peritonitis. There was hypostatic congestion of both lungs.

3. The third case was likewise one of intestinal obstruction in a young child aged $3\frac{1}{2}$ years, admitted on May 27. There had been vomiting and constipation since May 22, and it was stated that "blood and slime" had been passed the day before admission. I first saw the child on May 29, and immediately opened the belly in the middle line, and found a small intussusception in the right iliac fossa, which I reduced. The small intestine was extremely distended, and in attempting to return that which had escaped through the incision, the peritoneum was torn. The child sank and died in nine hours. At the autopsy there was lymph on the coil of intestine which had been wounded, for a length of two or three inches. The intussuscepted gut, which was the lower end of the ileum, was purple in color, but not inflamed.

4. The fourth fatal case was that of a woman, aged 31, whose night-dress caught fire and was completely burnt off her, inflicting burns of the first, second and third degree, extending over the whole of the right upper limb, the left forearm, right side of the face and neck, and the right half of the back, chest and belly. She died on the seventh day, the temperature ranging between 102° and 104° Fah. for five days, and standing at 105° at the time of death. At the autopsy there was found some congestion, but no ulceration of intestines; hypostatic congestion of the base of both lungs, with acute bronchitis.

5. The fifth case was that of a little girl æt. 8, admitted on June 16 with caries of the spine and iliac abscess; the abscess was aspirated on several occasions. She died on July 30 from tubercular meningitis. At the autopsy there was found an enormous abscess connected with the diseased bodies of the vertebræ, and some gray granulations scattered through the lungs and pia mater.

6. The next death was a woman æt. 65, who suffered from a scald of the third degree, of the buttock, the right and left thighs, and the right leg. The sloughs separated and the wound began to granulate well, but 3 weeks after admission she became delirious, constantly muttering or crying out, although she could at times be roused and answer questions. She died from exhaustion 5 days after these symptoms set in. At the autopsy the only notable change found was the hypertrophy of the bladder, with pus in both ureters and the pelvis of each kidney, and a small abscess in the left kidney.

7. The seventh case was that of a man 67 years of age who was brought to the hospital with a subcoracoid dislocation of the right shoulder. While attempting reduction by Kocher's method, the surgical neck of the bone snapped across, but under chloroform the head of the bone was replaced in the glenoid

cavity and the fracture "set." The patient was made an out-patient on the third day. Unfortunately, he was a man of intemperate habits, and after a debauch he fell and sustained an impacted fracture of the neck of his right femur. For this he was readmitted and treated with rest in bed and a long splint. He was a very troublesome patient. For a time all went well. Then he sank into a low state with muttering delirium, and died 33 days after his readmission.

8. The eighth case was that of a girl æt. 16, admitted on Dec. 22 with an alveolar abscess in connection with the lower jaw. When I first saw her this had burst into the mouth. The swelling gradually subsided, but some induration over the jaw continued for some time. On Jan. 14 all local symptoms had passed off, but she was very pale, anæmic and thin, and I ordered her some tonic medicine. Next morning she became cold and collapsed, complaining of diffused pain over the belly. I saw her and found her almost pulseless at the wrist, with retracted belly and no local indications of the cause of the collapse. I ordered hot applications, sinapisms, and hypodermic injections of ether. I saw her again at night, when she appeared to be moribund. On going to the hospital next afternoon I was surprised to find her alive, quite conscious and less cold than on the previous evening, but there was no pulse at the wrist, and it was only feebly felt at the groins. Thinking there might be some chance for her as she had lived so long, I gave her at once an ounce of champagne; the pulse at once became perceptible in the brachial artery; in an hour the champagne was rejected, and she appeared to be holding her ground, but soon afterward she suddenly fell back in bed and died. Unfortunately, we were not allowed to make any post-mortem examination.

9. The ninth and last case was of a woman who was admitted on the evening of Dec. 31, having been picked out of the Regent's Park Canal. She was almost dead on admission, and in spite of every effort at restoration, including sinapisms and injections of ether, she died just after midnight. No autopsy was allowed.

I have thought it right to give these details of all the fatal cases, and I do not wish to explain away the facts. I think, however, that they show that all classes of cases may be met with in this hospital, that a fair proportion of severe injuries and diseases come there for treatment, and that in so far the wards of the hospital will bear investigation. I cannot tell what impression the notes of these cases may make upon my hearers, but I may perhaps add that I did not feel in regard to any one of them *at the time* that alcohol would have saved or prolonged life. As stated, alcohol was given in one case, and in none of the others was it withheld on account of prejudice, but solely for want of a sufficient indication for its employment.

I cannot convey any impression as to the way in which the patients progressed day by day while under treatment without alcohol, and the cases are too few to warrant the employment of the statistical method, and with a far larger number I should hesitate to

adopt it. But it is not too much to say that they show the hospital to be actively engaged in the treatment of the same class of cases found in the surgical wards of any of the larger metropolitan hospitals, and that therefore its work is worthy of the careful attention of the profession. My object in this paper is not to show that alcohol may be or ought to be excluded altogether from surgical practice, but to show to how large an extent it can be dispensed with, with safety; and to express my conviction that its employment is not attended with advantage in a large majority of cases, while in many it is positively and seriously injurious. There is no stranger fact in the present-day therapeutics than the position held by alcohol. There is no disease and scarcely a single pathological condition for which it is not prescribed. It is a drug that never fails in the hands of the majority of practitioners; when cases improve the alcohol administered is invariably and without question accredited with no small share of the favorable result; when patients pass from bad to worse and die, the alcohol may have been given too late, or in too small doses, or have been overcome by a too-strong foe, but it certainly prolonged life and exerted a beneficial influence! Such, practically, is the argument of not a few practitioners, even if they hesitate to formulate it. The scepticism applied often so ruthlessly to other drugs has scarcely dared to hint that alcohol is not an all powerful remedy, able in one way or another to cope with any of the diseases of our frame. When the results of prescribing alcohol so widely come to be closely questioned, I am confident that it must lead every candid surgeon to restrict very largely the use of this drug. Without entering into a consideration of the physiological action of alcohol, or attempting to appraise its value in every class of injury and disease, I would submit the following propositions in regard to it:

1. *That alcohol is contraindicated in all cases where it is important to secure physiological rest!* I am aware that alcohol is a powerful narcotic, but I believe it to be a very rare conjunction of circumstances which permits of its successful employment as such without attendant evil from its stimulant effects.

2. *Therefore in the period immediately following operations and injuries*, especially large wounds such as in amputations and excisions, compound fractures, and severe hæmorrhage, *alcohol is contraindicated.* It is only admissible in those extreme cases where life is in immediate danger from failure of the heart, and in these cases we have in subcutaneous injections of ether a more potent stimulant.

3. *For exhaustive diseases alcohol is contraindicated except as a temporary stimulant*, and for the following reasons:

a. By increasing the frequency and force of the heart's action without at the same time proportionately increasing the nutritive activity of the heart, it hastens the exhaustion of that organ.

b. By dilating the small vessels it increases the difficulty with which the circulation is carried on.

c. By impeding the action of the digestive and assimilative organs it lessens the supply of nutritive material entering the blood. I have been much struck

by the appetite, the easy and regular digestion, and the absence of the common indications of gastric and intestinal trouble which patients who are not taking alcohol present.

d. By increasing the work thrown upon the lungs and the kidneys, the two great excretory organs of the body, alcohol hinders the proper depuration of the blood, and possibly hastens the occurrence of the hypostatic congestion of the lungs so prone to occur in these cases.

e. By its narcotic influence upon the central nervous system, it interferes with the due discharge of its functions.

4. *In alcoholism, whether acute or chronic, alcohol is contraindicated.*

RATE AND CAUSE OF MATERNAL MORTALITY IN 1,000 CASES IN PRIVATE OBSTETRICAL PRACTICE.

BY WILLIAM M. FINDLEY, M.D., ALTOONA, PA.

Read in Section of Obstetrics and Diseases of Women of American Medical Association, May, 1884.

While the rate of mortality, as given below, may be greater than that found in the experience of others, yet the writer apprehends that the causes as described, will make it appear that it is not excessive. The comparison between the same classes of cases in hospital and private practice, will show much more favorably if, as I think, due credit is given to the manifold obstacles which surround the practitioner in private circles. Called, as he often is, only "in extremis," when labor has progressed so far that a malposition which could have been readily corrected before the labor began, or in its early stages, has become an irremediable condition, is it any wonder that fatal results follow? Is it not the greater wonder that fatal results do not more frequently follow? Compelled to attend puerperal cases in the most unsanitary localities, and under the most unhealthy conditions, with no opportunity to remedy surroundings, or prepare the patients for the ordeal, is not the practitioner in private practice to be commiserated when comparison is made between him and those who serve in the hospitals surrounded with all the appliances of science and art to aid them; all the assistance required, either professional or otherwise, and in large majority of cases with time beforehand to prepare their bad cases for that which is before them, if, indeed, it be true that many of the fatal results follow uncleanness, this being the leading factor as at present taught in causing the septic troubles.

Hoping that others who have like statistics may present them for the purposes of comparison, and trusting that still others may have had yet smaller mortality rates, I offer this:

CASE 1. Woman, aged 23, first pregnancy, aborted

about the end of the fifth, or beginning of the sixth month. Septicæmia resulting from the detachment of a very firmly adherent placenta, leaving a very large portion of the uterine surface in an injured condition, and in whom neither internal medication, nor medicated injections locally produced the slightest relief.

CASE 2. Woman, aged 33, fifth pregnancy, was delivered in the same room in which lay two of the children of the family suffering from scarlatina. As she lived in a town ten miles away, and I was summoned by telegraph, arriving only to find her in the active throes of labor, and with no other place in the house to remove her to, she lay exposed to the scarlatinous poison, which developed in the characteristic pyrexia, eruption, etc., on the third or fourth day, and the end soon came. This case was attended for and in the absence of a practitioner who was already in charge of the scarlatina cases, and attended her after the delivery until her death.

CASE 3. Woman, aged 19, first pregnancy, was delivered in what bid fair to be perfectly normal condition, but who on the second day had a severe rigor, very high temperature, and in short time was covered with the scarlatinous eruption, dying on the fourth day.

CASE 4. Woman, aged 34, eighth pregnancy, who early in this pregnancy showed unmistakable signs of acute renal disorganization, fell into labor six weeks before the end of gestation, was delivered of a very small, feeble child, and in removal of the placenta, which gave no trouble, gasped, exhibited sudden indications of heart clot and expired, as it appeared to the writer, from the sudden absorption of additional urea into the circulation when the pressure exerted by the gravid uterus was removed.

CASE 5. Woman, aged 26, second pregnancy, had been under the care of a midwife, as they were all Germans, for 20 hours; when summoned, found it necessary to perform version, which was done, and delivery effected in a few minutes, patient left perfectly comfortable, although exhausted; as it was at some distance, the patient was not seen again, but was informed that she died in 24 hours afterwards—no history of excessive hæmorrhage, and attributed it to exhaustion or heart clot.

CASE 6. Woman aged 21, first pregnancy, labor only twelve hours in all, everything apparently normal until the end of the second day, when she had a very violent rigor, what was considered to be general peritonitis was developed, and she died at the end of the fourth day. There was a history of great mental depression here for a long time prior to the labor owing to unhappy marital relations.

CASE 7. Woman aged 36, in the 9th delivery, who had been greatly exhausted by frequent pregnancies and very severe labors owing to very marked pendulous uterus, was delivered by version after failure to put on the forceps, owing to the hydrocephalic condition of the head; was very much prostrated and notwithstanding every effort was made use of to aid her, the state of shock persisted for 19 hours, when she expired.

CASE 8. Woman aged 22 in her first labor, only

eight hours, was delivered of a healthy female child, without complication except a very slight laceration of the perinæum which was kept touched with astrin-gents and antiseptics, but who, owing to an injudicious nurse's action in giving her a heavy supper of meats, etc., within twenty-four hours developed septicæmia, ushered in by a rigor and following the usual course for six days, terminated in death.

CASE 9. Woman, aged 29, in her first pregnancy, having been in perfect health up to January 28, 1883, was seized with a sudden pain immediately under the third dorsal vertebra which became so severe that the writer was summoned within thirty minutes of the inception of the trouble, and administered a hypo-dermic of morphia which relieved the intense pain, but before doing so it was noticed that the lower ex-tremities were paralyzed, and that there was retention of urine. The pregnancy had reached the end of the seventh month without further details, except to say that it proved to be spinal apoplexy, and that although the greatest care was exercised, a bed sore as large as the hand formed over the sacrum in twen-ty-four to forty-eight hours, and abortion was advised on consultation, and brought about, nothing seemed to avail and death closed the scene on the eighth day.

CASE 10. Woman aged 43 in the 11th pregnancy, who had experienced great trouble in all her previous confinements, had a fall one week prior to the date of actual labor, and then lost a large quantity of blood, but as the flow checked up by rest she received no medical attention; again two days before the writer was called, she suffered the loss of what was said to be a great quantity of blood, and again no medical aid was summoned; finally on the evening of Nov. 7, 1883, she had another frightful hæmor-rhage, and on reaching the house I found her almost pulseless, and incapable of articulate speech; uterus high up; no dilatation of the os and no hæmorrhage at the time. As I could not reach the bag of waters to puncture, resort was had to the tampon, and large quantities of nutrient and stimulant liquids—the os dilated rapidly, labor progressed speedily and she was soon delivered without the loss of two ounces of blood additional. It appears to me that the whole process of labor was of the character which might best be described as ante-mortem, for the heart's action was very rapid and irregular, and she never gained complete consciousness during the time I saw her.

RECAPITULATION.

Septicæmia was accountable for two deaths.	
Scarlatina puerperalis	two “
Heart clot	one “
Renal disorganization	one “
Shock	one “
Spinal apoplexy	one “
Hæmorrhage, ante-partum	one “
Peritonitis, general	one “
Total,	ten deaths.

It will be apparent in this limited number of deaths that the septic element is still the great factor, and while this is true, may it not also be true that with all our knowledge there may be some cases of true, or

analogous to true, puerperal fever? a something more than mere sepsis introduced through a wound of the genitals. It is noticeable in the discussions of this subject in the New York Academy of Medicine that there were still manifested grave doubts as to total absence of something more than that which comes from without; although the weight of evidence was most in favor of infection through abrasions and wounds, rather than from a true autogenetic origin.

How to lessen the mortality in puerperal cases is a very important and interesting subject of discussion, and aside from the septic cases, the writer feels totally at a loss to know how to proceed or what to suggest in all the other conditions recorded as causing death from the standpoint of his personal experience. True, Dr. Busey in a late (April) number of the *American Journal of Medical Sciences* records a favor-able termination in a case of scarlatina puerperalis, but is that not an exception to a very general rule of the fatal issue of that class of cases? and as he shows is largely true only of those cases which are attacked late in the lying-in.

And what shall we do in heart clot and marked renal disorganization, and shock and spinal apoplexy? As for ante-partum hæmorrhage, I doubt whether my patient would have died had she been seen at or after the first loss of blood more than a week before she was first seen by me. I might have used intravenous in-jections of blood or milk, but the efficacy of such measures is still a moot question, and totally imprac-ticable in this case.

The great duty before the medical profession now is evidently the earnest endeavor to guard against septic infection in puerperal cases. It is the great effort in surgical treatment, and it matters little what measures are adopted so that perfect cleanliness is maintained, and such germicides are made use of as will destroy the noxious germs, not troubling our-selves about the multitudes of germs which are in-nocuous.

During the terrible epidemic of 1873, the writer was especially fortunate in having no septic cases ex-cept one case of scarlet fever, in the parturients com-ing under his care, while in a population of 10,000 or 12,000 there were a number of deaths, some 30 in all from that cause, rendering it a time of especial dread. These deaths, in very many instances, were among the class of women who were cared for by midwives, and frequently lacked all proper care, and, as I have been told, the disease often progressed so insidiously to the bad that danger was not appre-hended until all hope was passed.

The septic deaths occurred in order in the 66th, 524th and 659th cases from septicæmia and general peritonitis, and in the 166th and 229th of scarlatina puerperalis, one of them, viz., the 166th of scarlatina puerperalis, in the year 1873.

As hinted in the discussion at the Academy in New York, long periods may elapse between the deaths from septicæmia, and unless carefully recorded may easily be forgotten, especially as all like to forget fail-ures, unless willing to make them public for the gen-eral good, so that all mere assertions from memory

may and likely do prove fallacious, and the fact still remains that septicæmia is the one disease which we should most strenuously combat, and he who guards his parturient clientele most carefully from this insidious foe will be the one most fitted to practice his noble art.

In conclusion, as stated in a paper by W. W. Jagard, M.D., as to the Vienna mortality in Carl Braun's clinic being only one-half of one per cent. from septic diseases, it is with a feeling of something akin to self-gratulation that the writer notices that the mortality in his list is not much greater, and that his entire mortality, omitting the two cases clearly not properly included in his death-rate, is only three-quarters of one per cent.

MEDICAL PROGRESS.

ANATOMY AND PHYSIOLOGY.

OBSERVATIONS ON A DECAPITATED HEAD.—The observations related by Dr. Petitgrand, in a paper published in the *Revue Scientifique*, extracts from which are given in the *Medical News*, are highly important as furnishing the most precise evidence of the presence of consciousness after decapitation that exists. The man executed was a pirate, of robust frame and brave demeanor. He was an Annamite, and executed at Saigon. M. Petitgrand concentrated his whole attention upon him. He was placed in a kneeling posture, strongly attached to a solid post in front of him, with the head and neck voluntarily and strongly flexed.

The place for the blow having been marked with betel juice, the head was struck off at one blow by means of a long sword having a broad blade; the procedure, to be properly carried out, requiring great address on the part of the executioner, and much *sang froid* on that of the culprit. When this is the case there is, of course, far less contusion and concussion of the spinal cord than with the guillotine, and therefore so far a greater possibility of an ulterior manifestation of the functions of the encephalon. During the preparations Dr. Petitgrand never withdrew his eyes from the culprit, placed at two metres distance only, and with whom he more than once exchanged looks. The head fell within a metre and a half from him, without, as ordinarily, rolling away; and the divided part of the neck resting on the sand, the hæmorrhage which ensued was very slight. At this instant he was startled at finding the eyes of the head steadily fixed on his own, and not believing that this could be an act of consciousness, he rapidly described a quarter of a circle around the head, which lay at his feet, and saw plainly the eyes following this movement. He now returned to his former position, but more slowly, and the eyes followed him for "a very short instant," and then suddenly ceased to do so. At this moment the face expressed manifest anguish, the poignant anguish of a person in a state of acute asphyxia. The mouth opened violently, as if to take a last gasp of respirable air, and the head,

thus displaced in its equilibrium, rolled on its side. This contraction of the maxillary muscles was the last manifestation of life, a period of from fifteen to twenty seconds having elapsed since decapitation.

From these facts Dr. Petitgrand draws these conclusions: (1) That the head separated from the body is in possession of all its faculties as long as the hæmorrhage is restrained within certain limits, and that the proportion of oxygen dissolved in the blood is sufficient for the maintenance of the nervous function—that is, for a short period, which in any case would not exceed half a minute. (2) That the repeated convulsive movements of the lower jaw, after the head has become detached—movements which, without doubt, have given rise to the expression, "biting the dust"—are nothing else than the habitual reflex movements of the face in acute asphyxia. These cannot be absent when the little blood contained in the decapitated head flows away or becomes disoxygenated, and are caused by the sensation (probably conscious) of the want of necessary oxygen in the blood remaining in the encephalon. On the present occasion Dr. Petitgrand had no opportunity of observing the trunk of this beheaded man, but he has had opportunities of observing it on other occasions, and has always noted the following circumstances: The head once detached, the trunk (the body being attached by cords to the post, is unable to fall) suddenly assumes the vertical position, columns of arterial blood springing up a metre or more in height. This straightening of the trunk, and the jets of blood being simultaneous, are in fact related to each other as cause and effect; for at each new systole, manifested by the projection of a column of blood, the trunk is raised, to bend again immediately. The jets soon do not ascend to more than a few centimetres, and the movements of the trunk are reduced to mere oscillations. After from twelve to fifteen systoles all the blood is evacuated and the trunk remains motionless, and as it were suspended to the post, which prevents it falling on the ground. Dr. Petitgrand has never noticed any elevation of the ribs or sinking of the epigastrium, or any other sign of an attempt at respiration. The heart seems to continue to live awhile its own proper life, as is shown by its violent systoles, which are capable of affecting the stretching of the trunk.

SURGERY.

TREATMENT OF NASAL POLYPUS BY SODIUM ETHYLATE.—Dr. B. W. Richardson, in the *Asclepiad*, gives the following treatment for cases of polypus of the nose. He uses a long and slightly curved pair of steel forceps, the ends of which come to a fine point. He takes a piece of soft cotton wool, places it between the points of the forceps, and, twisting it firmly round the points, makes it into a good-sized, soft, flexible probe, like the end of a bougie. He saturates the cotton probe with the sodium ethylate, and then, having caused the patient to bring the polypus into view by sharp blowing of the nostril, he plunges the cotton, charged with the ethylate, into

the polypus, and retains it in position for two or three minutes. On removing the cotton it commonly happens that the patient can expel the whole mass of destroyed polypus, in a semi-fluid form, by again blowing the nose sharply.

After the substance of the polypus has been destroyed, a second cotton probe, treated with ethylate, as before and passed along the nasal cavity to the point at which the polypus seemed to be attached, will destroy the basis of the growth as well as the growth itself.

The modus is sufficiently clear. The ethylate solution, in contact with the water of the polypus, is decomposed into caustic soda and alcohol. The alcohol coagulates the albuminous part of the mass, and the soda acts as a destructive caustic on the surrounding parts, so that the point of attachment is destroyed. This mode of treatment, like that of the actual cautery, and the tearing process by the forceps, is painful. It is not a prolonged pain, and it ceases almost immediately after the operation is completed. There has been no instance of hæmorrhage, neither have there been any severe signs of inflammation, nor of foetid discharge.

TREATMENT OF BUOES BY ASPIRATION.—Mr. Weston, in the *Indian Medical Gazette*, refers to two cases of bubo successfully treated by Surgeon-Major Hogg by means of the pneumatic. "The men," he says, "went out of the hospital much sooner than they would have done had the buboes been laid open. In one case the operation had to be repeated once. A pad and bandage were used after the pus had been drawn off. In our military hospitals, where the ordinary plan of laying open the bubo is practiced, one often sees the resulting sore take on an unhealthy action, and, as a consequence, the men are kept in hospital for several months. It would be well, therefore, to give the aspiration treatment a thorough trial."—*Medical Times*.

GALVANOPUNCTURE IN ANEURISM OF THE AORTA.—Dr. Francesco Brancaccio, in the *Revista Internaz di Med. e Chir. (Practitioner)* reports the case of a man æt. 64 years, of intemperate habits, who complained of pain in the left anterior part of the chest, over the base of the heart, which radiated to the shoulders. The pain came on suddenly after a muscular effort, and was intermittent. Examination revealed a tumor, limited above by the upper border of the second rib, on the right by the sternum, on the left by the mammary line, and below was continuous with the heart. The diagnosis of aneurism of the ascending portion of the aorta having been made, it was determined to practice galvanopuncture. A fifteen-cell Daniell's battery was used, two needles being carried into the sac through the third interspace to a depth of $1\frac{1}{5}$ inch, and $1\frac{1}{2}$ inch apart. The first sitting lasted sixteen minutes. In the afternoon the patient felt better, the tumor was smaller, the pulse, which had fallen from 118 to 90, was stronger, and the respirations were less frequent. Twenty days afterwards the battery was again used, with twenty

elements, for fourteen minutes. Altogether it was used four times, and the patient was completely cured.

CASE OF INTESTINES ADHERENT BEHIND UTERUS, CAUSING INTENSE PAIN, RELIEVED BY ABDOMINAL SECTION.—Lawson Tait, F.R.C.S., relates the following in the *Medical Times*: S. B., aged 32, presented herself at the Birmingham Hospital for Women early in November last, complaining of constant pelvic pain dating from her last confinement, and much aggravated by the patient having "strained herself" six weeks before. On examination, the uterus was found to be somewhat fixed with a mass behind it, very tender on pressure, and clearly cystic. But for the fact that she complained of no increase of pain before or during menstruation, I should have diagnosed the case to be one of occluded and distended tube. As it was, I made no diagnosis, but advised abdominal section. This the patient readily agreed to, and I performed it on November 8. I found a good deal of matter in the pelvis, and a coil of intestine adherent in the cul-de-sac. I undid the adhesions without much difficulty and closed the abdomen. She left the hospital on November 28, and has been entirely free from pain since. I have just seen her (July 7), and find that she has had no return of her old symptoms, and is in perfect health.

This case is a very instructive one, for the physical signs were precisely those of pyo- or hydro-salpinx; and if it had happened that the patient had suffered much at menstruation, I certainly should have set it down as a case of one or other of those diseases. Suppose that, under this belief, I had acted as some (who have had no experience) advise, suppose I had tapped from below, I should have done no good; I should probably have made my patient worse; I might even have killed her. On the other hand, following my rule of opening the abdomen, I was able, with very little difficulty, to cure completely a condition which distressed the patient, which put her in constant risk of her life, and for which no other remedy was possible.

MEDICINE.

INTESTINAL SEPTICÆMIA.—This subject, which has for some time been a question for discussion as to whether it is possible that the absorption of putrid material developed in the intestine could produce septicæmia, has its illustration in a case given in the *Lyon Medical (Lancet)*. The patient, a man aged 44, was first treated for a strangulated gangrenous hernia of the right inguinal region. It was deemed advisable to make an artificial anus, and it turned out that this unnatural opening led into the ascending colon, and not into the small intestine. All was going on well for months, when one day, without any obvious cause, the patient became delirious, a scarlatiniform rash appeared on the whole surface of the body, the pulse increased in frequency, the pupils became greatly dilated, but there was no pyrexia. The fauces were not inflamed, though the throat was

said by the patient to be dry, but no lymphatic enlargement could be detected. The rash did not disappear. The symptoms could not be laid to the charge of belladonna or any other medicament, for the patient had not taken any drug whatever. As Zuelzer and Sonnenschein have extracted from putrid liquids a ptomaine giving rise to all the toxic properties of atropine, the physician in charge, M. Lépine, made the diagnosis of auto-intoxication by an atropic ptomaine. This hypothesis fully explained the strongly dilated pupils and scarlatiniform rash, and other symptoms, as well as an intense conjunctivitis which appeared later on, as did also an irregular pyrexia. The man died of asthenia. The necropsy revealed a horrible state of the large intestine beyond the artificial anus. The colon contained a putty-like mass, extremely fetid, and it is said of an odor *sui generis*. It seemed that the washings of the bowels, which had repeatedly been made, were totally inefficacious.

TREATMENT OF ASIATIC CHOLERA.—Dr. F. E. M'Farland, Honorary Brigade Surgeon, gives the result of thirteen years' experience in India in a paper in the *Dublin Journal of Medical Science*, and speaks strongly in favor of permanganate of potassium. He considers in order the following plans of treatment:

1. The calomel and opium treatment.
2. The salt treatment.
3. The belladonna treatment.
4. The permanganate of potassium treatment.

He dismisses the calomel and opium treatment with a few words. He has seen many cases recover under it. Some cases will recover in spite of any treatment as some will die; but he thinks the treatment adds much to the agony of the disease, and if it does not hasten the patient to the grave, does not smooth the passage. It may be laid down as a rule that opium should never be given once collapse sets in.

The second is the salt treatment, and there are two ways to use it. One is, common salt, 3ij; bicarbonate of sodium, gr. 36; chlorate of potassium, gr. 10; water, 3viiij; to be taken every half hour or hour, according to the symptoms. The other way is, half an ounce of common salt in a pint of water every half hour or hour. He has seen the mixture act very successfully, and more so than the plain salt and water. One would imagine either of these a nauseous draught; but anyone who has seen the avidity with which a cholera patient will suck down the last drop thinks otherwise.

The salt treatment has been referred to as follows: "More cases of cholera have recovered with the salt treatment, and more cases have died, than under any other," and he cannot speak more clearly of it.

The third plan is that of belladonna. There is some reason in this treatment. Belladonna is a sedative of the sympathetic system, which is the system affected in cholera. The form recommended is $\frac{1}{4}$ grain of extract of belladonna with gr. 2 of sulphate of quinine, in a pill freshly made up, every half hour or hour, till reaction is established. The

belladonna treatment requires constant watching, is very trying to the physician, but is a method of treatment worth knowing of.

The fourth plan of treatment is permanganate of potassium, and is certainly, he says, the most successful he has seen. It has many things to recommend it. In the first place you can carry a small bottle in your waistcoat pocket, sufficient to treat hundreds of cases, and no other medicine is necessary; in the next it is a pleasant remedy. From beginning to end there is nothing in the treatment to cause apprehension to the patients or add to their sufferings. The plan adopted is to give a teaspoonful of a palatable solution of the pure salt every ten minutes, regularly, by the watch, until reaction is established, and then give beef tea, etc. One grain to four ounces of pure or distilled water is the strength of the solution required. The salt must be pure, and the solution must be renewed if it become discolored, as it sometimes does. Condry's Fluid will not do. Dr. M'Farland treated one case for six hours before any material sign of improvement took place, and after sixty doses reaction became thoroughly established, and the patient made a good recovery. At the same time another man was attacked, and his symptoms were relieved in less than two hours. With the permanganate treatment the patient may drink water freely, or, what is better still, meal and water, *warm*. The only thing is not to give the drink just on top of the permanganate, but wait three or four minutes. Some object on account of the smallness of the dose which is homœopathic. One medical officer gave it in $\frac{1}{4}$ grain doses; and this caused a burning sensation to the patient's throat, and added to his sufferings.

If more than a teaspoonful be given it is rejected, like everything else. The first symptom relieved is the sickness, then the thirst, then heat returns, purging and cramps cease, and after some hours the kidneys act.

As to accessory treatment, *drinks* he approves of, but does not see why ice is so much recommended, he has found that patients will enjoy drinking from a can of water into which a good handful or two of oatmeal has been put when it was hot, just as much as any other liquid. It is fluid they want, to supply the loss of water in the blood, and they will take it in any form. *Handrubbing* he thinks is often done too roughly—that the assistant should lubricate the hands well with warm oil, and knead, press, and squeeze the affected parts rather than rub them. For *injections* he would be inclined to try large quantities of a dilute solution of permanganate of potassium, as warm as the patient could comfortably bear, or large quantities of salt and water, with chlorate of potassium, well diluted and warm. As to *bleeding* he believes he has seen one remarkable case of recovery, where, after opening the vein, he could only squeeze out a few drops of black blood, like tar, but soon after he bled profusely and never had an unfavorable symptom afterwards. He believes in the *non-stimulant* plan of treatment.

THE DEMONSTRATION OF SYPHILITIC INFECTION BY VACCINATION WITH LYMPH FROM A SYPHILITIC CHILD. INEFFICIENCY OF EXCISION.—The advance guard of medicine of the present day is unquestionably exacting. The general spirit corresponds to the Laconic phrase in use among the speculative class—"put up or shut up." Demonstrate or cease your pretensions. It would seem as though the nature of syphilitic virus had wrought such devastations and developed under such circumstances that its capacity of operating through the vaccine lymph would be accepted by the most incredulous. Moreover there are not wanting in journalistic literature records which seem to verify the assumption. It is perhaps true that they may not bear the severe crucial tests to which indisputable facts are of necessity subjected. For practical guidance, however, one might have supposed the circumstantial evidence as satisfactory. But science says, no. Nothing but absolute demonstration. Here, as in other phases of life, the demand creates the supply.

Dr. Cory,¹ of London, as quoted by the London *Med. Record*, has experimented on himself "to test a current belief that vaccine lymph taken from a syphilitic person, if unmixed with the blood of the vaccinifer does not contain the syphilitic virus and is incapable of imparting syphilis by its inoculation." The report was made by very able observers, among whom is the well-known name of Jonathan Hutchinson, the other members of the committee being Drs.

Bristowe, G. M. Humphrey and Ballard. Three experiments failed to impregnate the system, although all the children from which the vaccine lymph was taken were affected with genuine syphilis. The first experiment was made in 1877 or 1878, the fourth and successful one in 1881.

On July 6, 1881, C. caused himself to be vaccinated in three places with lymph — no admixture of blood — from the vaccine vesicle of a syphilitic child's arm, the immediate neighborhood being free from syphilitic eruptions. The vaccination was unsuccessful, but on July 26 (21st day) Dr. Cory observed that two of the places were red, in fact, papules. August 11, Dr. Cory showed his arm to Mr. Hutchinson and Dr. Humphrey, both of whom considered the spots to be syphilitic. And, as the sequel showed their diagnosis to be correct, the demonstration of the possibility of conveying syphilis by lymph from a vaccine vesicle was established. One important lesson which it would be wicked not to appreciate from this self-sacrificing experience is the possible danger of humanized virus. There is no practitioner who has not overlooked cases of syphilis, and no one can be in a position to say this or that child is not tainted with syphilis. Hence, the almost universal custom in America of using bovine virus is to be commended.

There is still another lesson of considerable import connected with the case. Dr. Cory did not hesitate as soon as Mr. Hutchinson and Dr. Humphrey, 36 days after the introduction of the virus, pronounced the sores syphilitic, to have them excised with all necessary and due precaution. Notwithstanding the excision, however, on the 31st day of August roseola developed on the forehead, temples, back of the neck and below the ears, also on the lower part of the abdomen. So that in this definite instance the excision of the chancres did no good as far as the prevention of the disease was concerned. This one circumstance must have its influence in modifying the enthusiasm developed in certain quarters of excising a supposed chancre.

"CHILDREN OF THE SIEGE."—Such is the name applied in France to those unfortunate children who were begotten during the siege of Paris in 1871. We call them unfortunate, because conceived of mothers, who, torn alternately by the conflicting emotions of hope and despair, and too nearly famished themselves to spare requisite nourishment for their offspring *in utero*, were nevertheless compelled to yield to the lust of half-drunken husbands. Begotten of such parents amid the "horrors of the Commune,"

¹ Supplement of the Twelfth Annual Report of the Local Government Board.

these "Children of the Siege" came into the world puny and misshapen. M. LeGrand du Saulle, one of France's most celebrated alienists, has stated that out of ninety-two such children examined by him sixty-four were crippled in mind or body; out of this number thirty-five showed malformations and twenty-nine were imbecile. There is nothing surprising in these facts. They are but impressive, because exaggerated illustrations of what we see about us daily; children born of want and intemperance. Is it any wonder that they grow up to beggary and crime. The lives of these "Children of the Siege" contain a lesson for us physicians, as well as for Ladies' Aid-Societies.

M. Legrand du Saulle, in the same address delivered last April, brought out some interesting facts concerning the increase of insanity in France since the Franco-Prussian hostilities. He has examined 35,000 insane, at the Prefecture, in the past fourteen years, and concludes that the intense excitement of those days is responsible in many cases for the mental alienation, having either produced it directly, or precipitated its manifestation. Furthermore, he attributes the increased insanity of this latter half of the century to thirst for pleasure, pursuit of wealth, speculation in stocks and intemperance, which last was the exciting cause in 25 per cent. of his cases. Again, is there not a suggestive lesson here for us of America. Our people are not given up to a search after frivolous enjoyment, as are the French, chiefly the Parisians, with whom it is an absorbing passion apparently, nor is there here that consumption of absinthe which is accredited with the speedy production of serious brain disease; but the excitement of our stock exchanges and boards of trade, high pressure in other branches of business, and the great consumption of alcohol, are evils against which physicians, as conservators of the public health, should raise a vigorous protest.

PROGRESS OF CHOLERA IN EUROPE.—During the week ending Sept. 8, despatches show that the epidemic cholera has been making but little progress in France and Spain, but has extended much more rapidly in Italy, the scourge prevailing very severely in Naples. In the city just named, 451 new cases and 154 deaths are reported as having occurred during the twenty-four hours preceding the evening of the 8th inst. A large part of the inhabitants are represented as panic stricken, and as resorting to superstitious rites and ceremonies to a degree that would have disgraced the inhabitants in the darkest ages of human history.

THE LONDON TEMPERANCE HOSPITAL.—It is with much pleasure that we give our readers, in the present number of the JOURNAL, the paper presented in the Section of Surgery and Anatomy of the American Medical Association, at its meeting in May last, by Dr. A. Pearce Gould, of London, containing the results of one year of practice in the surgical department of the London Temperance Hospital. The facts and statistics presented, and the sentiments accompanying them, are worthy of the most careful consideration, especially by that large class of medical and surgical practitioners who practically use alcohol in some form, as though it was a universal panacea for human ills.

THE AMERICAN ASSOCIATION FOR THE ADVANCEMENT OF SCIENCE, in annual session in Philadelphia during the past week, has been largely attended, and much valuable scientific matter has been presented in the various Sections. The interest manifested and pleasure enjoyed in the receptions and social relations of this anniversary, have been greatly increased by the very large number of foreign visitors present.

THE LATE DR. GRAFTON TYLER.—The interesting biographical sketch of the late Dr. Tyler, so long and well known in Washington and Georgetown, which was unexpectedly crowded out of our last week's issue, will be found under the head of Necrology in the present number.

PRICKLY HEAT.—Mr. Henry T. Wharton in the *Lancet*, records a case of this distressing affection in a medical man who was subject to it each summer, after passing the age of thirty years, until it became intolerable. From the conspicuous follicular lichenous inflammation on his back, he could not bear to take a Turkish bath in public or to turn up his shirt sleeves in ever so troublesome an obstetric case. From May to November he was a martyr to his troublesome malady. He consulted all his friends and more than one distinguished specialist. His efforts to get cured were as unrelenting as they were unavailing. At last the idea occurred to Mr. Wharton that perhaps the tight short-sleeved India-gauze undershirts worn in the summer were too thin either to absorb the perspiration, or to protect the skin from sudden (but perniciously grateful) chills. They were changed for the thickest long-sleeved undershirts made entirely of wool, such as worn in the depth of winter, resulting in the absolute cessation of his experience of "prickly heat." For years he suffered a transient attack of urticaria—itching without any outward signs, after a cold bath. Since he has taken to the constant use of hot water for all his ablutions, this irritation has never returned.

SOCIETY PROCEEDINGS.

CHICAGO MEDICAL SOCIETY.

Regular meeting September 1, 1884. "Remarks on Aneurisms," and exhibition of a large specimen by Dr. J. A. Robison.

Recent Treatment of Asiatic Cholera, as in vogue in Southern India, by Dr. H. M. Scudder.

"Remarks on Aneurisms," and exhibition of a large specimen of an aneurismal sac of the arch of the aorta, involving the aortic valves, was the title of a paper read by Dr. J. A. Robison. The following abstract which has been prepared by the Secretary we here-with append. We omit giving the etiology, pathology, and diagnosis of aneurisms, and proceed to the general principles governing their treatment, which have been to prohibit the patient from taking much exercise, to secure as nearly as possible absolute rest, and to restrict the diet. Where the heart was tumultuous, cardiac sedatives were exhibited. Such symptoms as dyspnoea, pain, etc., have been met with appropriate palliatives. The first attempt at specific treatment for internal aneurisms was employed many years since by Albertini and Valsalva, and has been known as Valsalva's method. It consists in weakening the patient by repeated blood-lettings, and by gradually diminishing his meat and drink till only half a pound of pudding was taken morning and evening, with only a measured quantity of water; so that at last the patient was so exhausted he could not lift his hand from the bed in which he was ordered to lie from the commencement of the treatment. When this stage was reached the amount of nutriment was increased until the patient's strength was restored. It is needless to say that this plan of treatment did not yield the beneficial results which were anticipated. In our day it would be regarded as barbarous were we to try and enforce it to the extreme to which Valsalva reached. A modification of this treatment, consisting of enforcing absolute rest in bed, and diminishing the food and drink, so as to diminish the quantity but not the physiological quality of the blood, has benefited a number of cases, if not entirely cured them. While some physicians have refused to employ the depleting treatment, they have resorted to measures fully as severe. Dr. Murchison and Mr. Moore, of England, have recommended, and in one case tried, the introduction of fine wire into the aneurismal sac, on the theory that the large amount of surface exposed to the circulating fluid would produce coagulation of the fibrine. In the case referred to they introduced twenty-six yards of fine iron wire into the aneurismal sac, and it is needless to say that the treatment was unsuccessful, although they contend that the result obtained demonstrated the principle was sound, and that further experiments were justifiable. A much less dangerous and probably more efficient mode of treatment is by electrolysis. Pravaz was the first to use electrolysis for reducing external aneurisms, and Cincelli and others have applied it to internal aneurisms, but with very different results. Its employment has been extended to thoracic and

abdominal aneurisms, but in eight cases of thoracic aneurisms only one was benefited; the others being unsuccessful. Only one case of abdominal aneurism was cured, and this patient died from rupture of the sac, on account of premature exertion. The results obtained from the use of the galvanopuncture have not justified us in expecting to hope for much from that method. Professor Langenbeck has published accounts of two cases which he claimed to cure by hypodermic injections of one-half to three grains of Bonjean's watery extract of ergot every three days. Balfour says he has tried this method frequently, but without any success, although he was positive that his ergot was active.

Pressure as a mode of treatment is wholly inapplicable to thoracic aneurisms, and rarely to abdominal. Dr. Murray records a case of abdominal aneurism in which pressure on the aorta for five hours, the patient being under chloroform, was successful.

We will now speak of the treatment of internal aneurisms by the administration of the iodide of potassium. It is conceded by Flint and Bramwell, and insisted on by Balfour, that the iodide of potassium is the only drug which offers any hope of cure, and that in every case it will relieve the distressing symptoms, if it does not effect a cure. Balfour says: "Of all the various modes of treating internal aneurism, there is not one hitherto mentioned which is not attended with considerable risk or danger, except Mr. Tufnell's plan of perfect rest, while the advantages to be derived from some of them are, to say the least, very problematical." But the treatment by the iodide of potassium, of which the author now writes, is perfectly safe and free from all risks, and it is equally certain to afford relief, at least no case has been yet found where relief was not attained, though naturally enough that relief is not always to be got instantaneously, but requires the treatment to be continued for some time. It also relieves the pain and other symptoms of aneurism more rapidly and more effectually than any other treatment, apart even from the powerful agency of the recumbent posture; and for the time it has been in use it has given greater and more permanent relief to a larger number of cases of aneurism than any other mode of treatment whatever. Indeed the relief to the pain and other symptoms is so great and so speedily obtained, usually from the action of the drug alone, that it is often difficult to get the patient to submit to any restrictions, besides it is not always necessary. The author has employed this method of treatment during the last eight years in a very considerable number of cases, with unvarying success so far as the relief to symptoms is concerned, and with such favorable results as to retarding the farther progress of the case, and even in some cases promoting an apparent cure, as certainly to stamp this treatment as one of the most efficient hitherto propounded for the relief of this intractable complaint.

Balfour relates the history of twelve cases treated by this method with the following results: the symptoms such as pain, dyspnoea, etc., were relieved in every case; the physical signs of aneurism were diminished in seven cases, pulsation of the tumor

ceased in two cases, diminished in four, and was not apparent from the commencement in six. The aneurismal tumor disappeared in three cases, and diminished in five; the bruit disappeared in two cases and diminished in two cases, but never existed in two cases. Five of the patients were so relieved that they could work, four were discharged at their own request, feeling well, one patient absconded, and the result of treatment in his case is not known. Five cases were termed cured, and seven were not cured but relieved. One of the twelve cases referred to was an aneurism of the innominate artery, which was cured, and Balfour claims to have cured several cases of aneurism of this artery. One of the four cases discharged at their own request was under treatment three different times, being discharged twice at his own request, but died suddenly while under the third course of treatment, the autopsy revealing an aneurism of the aorta which had ruptured into the lower lobe of the right lung. One of the twelve cases was diagnosed as a weeping aneurism, implicating the origin of the left carotid, and communicating by a small opening with the left bronchus, the patient on admission expectorating arterial blood, but this soon ceased and the patient was discharged cured. While the writer did not believe he was justified in being as enthusiastic in the praise of the iodide of potassium treatment, as Balfour, he did believe he was justified in relating the following case, and giving the iodide of potassium the credit of prolonging the patient's life and making his life comparatively comfortable:

John H. C., aged 40, a blacksmith, was first seen in March, 1883. Had had attacks of inflammatory rheumatism several years ago. In February, 1883, was attacked with severe pains in the chest, in the præcordial region, and was treated by his physician for rheumatism for some weeks. Dr. J. P. Ross saw him and diagnosed aneurism of the aorta. At this time he had a good deal of dyspnoea, some hoarseness of the voice, and quite a little difficulty in swallowing solid food. When fatigued the pains in his chest were excruciating. No tumor was perceptible, although there was pulsation in the upper sternal region, and dulness upon percussion over the area of pulsation. Two months afterward there was a swelling in the upper sternal region at the junction of the left first and second ribs, about the size of a silver dollar. A very slight bruit was heard. The voice was very husky, and the difficulty of deglutition had increased until now the patient could take no solid food whatever. He had emaciated and was losing strength very rapidly. He was ordered to lie in bed continuously, and was given 15 grains of the iodide of potassium three times daily, gradually increasing the dose until signs of iodism appeared. It was truly remarkable how soon after this plan of treatment was inaugurated, the patient expressed himself free from pain and the distressing symptoms from which he had suffered. He persevered this way until May, when he said he was so well and weary of the bed he would like to sit up. Leave was granted. A few weeks after, the writer was surprised to see him walk into his office. The patient complained of nothing. He was cautioned against such experiments, and he was

told to return home and take better care of himself. His condition at this date was as follows: the continued pulsation of the tumor against the chest-wall had produced absorption of a large portion of the manubrium and an inch of the inner portion of the left first and second ribs. Consequently there could be felt the pulsations of the tumor through the chest-walls at a point where only soft tissues intervened. No bruit was discernible. On laryngoscopic examination we found complete paralysis of the left vocal cords. His voice was anserinous. During all these months he had been taking the iodide of potassium without any disturbing effects, until now, when he complained of symptoms of iodism. He was permitted to discontinue its use. From the date of this office visit he grew rapidly worse. He rapidly emaciated, dyspnoea and dysphagia increased, and finally he died of asthenia July 19, 1884, about 17 months after he began treatment.

Autopsy.—On opening the thorax a large aneurismal tumor was seen behind the sternum, about five inches in diameter. Friable adhesions of the sac to the sternum were broken up when the sternum was removed. Absorption of a large portion of the sternum and the left first and second ribs had taken place. Heart and pericardium were normal. Adhesions between the aneurismal sac and the left lung. The left lung was pressed upward and backward into the left pleural cavity, and collapsed. On opening the heart find the aortic valves roughened. Extending the incision into the arch of the aorta, find it dilated and at the anterior of the arch between the origin of the innominate and the left carotid arteries, an opening, oval in form, one inch by one inch and a half, into the sac of the aneurism. Through this opening the walls of the aorta were continuous, forming the wall of the aneurism. The tumor was firm, being composed of coagulated fibrine, and was then shown. Dr. Robison answered a number of informal inquiries relative to it, when Dr. John Bartlett cited briefly the history of a case of general chronic bronchitis and asthma, occurring in a man 70 years of age, who was supposed to be suffering from consumption for 50 years. Eight years ago when the patient came under his observation, he ordered him to take eight grains of iodide of potassium three times a day. He has not omitted a day since to take the medicine, and he has steadily improved, his kidneys have performed their natural function, his appetite has not been impaired, and he has grown fatter and stronger. The case is an illustration how long a patient may take iodide of potassium continuously without injury to the mucous membrane of the stomach or injury to the kidneys.

These remarks were followed by the reading of a paper entitled "The Recent Treatment of Asiatic Cholera as in vogue by European Surgeons of late years in Southern India," by Dr. H. M. Scudder. An abstract of which is published as under, will be read with much interest at this time, inasmuch as the writer favors a particular mode of treatment in this disease. It has been his lot during nine years' practice in India to pass through four epidemics of cholera and have the disease. He was the only European

physician in a town of nearly 50,000 inhabitants, and was at the head of a district hospital supported by the English Government and was called upon to treat a large number of cases.

One of the severest of these epidemics occurred during the famine of 1877-1878. The writer was at the time assigned to take medical charge of a large enclosed famine relief camp containing over 5,000 persons, and where often as many as 300 at a time were ill with the disease in the hospital sheds, with a death-roll during the height of the epidemic of over 50 per diem. In this camp he had the opportunity of trying, on an extensive scale, different remedies and the various modes of treatment and comparing the results. We will not take space by the enumeration of the long list of remedies that have been made use of in the treatment of cholera, or by the discussion of the value of the numerous and various forms of treatment that have been advocated, but confine this synopsis substantially to giving a description of the mode of treatment that is now employed near Madras and Calcutta. Before passing on to the subject proper, a word may be stated in reference to the writer's views upon the contagiousness of the disease. Said he: Cholera is an infectious disease and also somewhat contagious, though not highly contagious, or readily communicable by personal association with the sick as is the case with small-pox and measles. The noxious power of the cholera germ or virus (whether it is Dr. Koch's microbe or something else) seems to be more powerfully exerted sometime after it has escaped from the body of the patient than when it is freshly passed. From careful observation, study and experience in four epidemics of cholera, he has deduced the following, that the attendants and those who come into frequent and close contact with cholera patients are somewhat more apt to contract the disease than those who do not.

For purposes of treatment the writer divided the course of this disease into the following stages:

- (1) A period of prodromes or prodromic stage.
- (2) A first stage or stage of diarrhoea, or choleric.
- (3) A second or stage of invasion.
- (4) A third or stage of collapse (algid state).
- (5) A fourth or stage of reaction.

This last stage may be succeeded by a typhoid condition, or cholera typhoid state, or the patient may pass directly into a state of convalescence. In the prodromic stage, manifested by lassitude, mental depression, chilliness, nausea, and abdominal discomfort, give 10 or 15-drop doses of spirits of camphor in dessertspoonful of hot brandy every hour or two, but be careful not to allow any considerable quantity of stimulants to be taken. When epidemic cholera is prevalent, many are affected by the symptoms just described. If the remedies indicated were promptly taken the writer is confident that many attacks of cholera would be warded off. It is true that fear often produces these very symptoms, but the spirits of camphor in spoonfuls of warm brandy tends to soothe the fears and dissipate the symptoms, and yet it does not usually disorder the digestion. As soon as diarrhoea supervenes, the administration of preparations

of opium together with aromatics, camphor, and a little chloroform is urgently called for.

Two parts chlorodyne to one of spirits of camphor is a very good combination, 30 drops to a dose, to be repeated as required.

Another very serviceable preparation consists of equal parts of spirits of chloroform, spirits of camphor, laudanum, aromatic tincture of rhubarb, and tincture of ginger. Teaspoonful doses every hour or two, according to the urgency of the case, or until four or five doses have been taken, alternating with either of these three combinations, an aromatic sulphuric acid mixture may be given to advantage.

A popular formula is as follows:

R Acid sulphuric aromat 3i

Tincture opii deodorat 5 vi. vel. . . . 3i

M. Sig. 20 or 30 drops in water every hour or two.

The writer suggested the importance of administering these remedies hot, unless they create nausea. The hot water (2 or 3 tablespoonfuls) in which the doses are given may be sweetened if desired. The patient should be required to lie down, and be kept perfectly quiet, covered with heated blankets, and dry heat applied to the surface of the body, especially to the extremities, by means of heated flatirons, hot bottles, etc. In India the administration of calomel to any extent has lately been discouraged. One or two doses may be given if thought best, but not more. As soon as frequent vomiting commences, or stage of invasion becomes established, the combinations containing opium, which have been mentioned, had better be discontinued, and either of the following mixtures given instead in teaspoonful doses at intervals after a spell of vomiting, while at the same time some morphine or morphine combined with chloral, should be administered by hypodermic injection, as the severity of the case demands. Either of the following formulæ may be chosen for exhibition internally every half hour or hour, just after vomiting:

R Chloroform, tincture capsici, tincture canab. Ind. aa ʒxxx, acid hydrocyanic (dil.) ʒxx, ether ʒviii, spirits menthæ pip. ʒxv, syrup sassafras comp. ad ʒis. M. S. A small teaspoonful every half hour or hour.

R Spirits ammonia aromatic, spirits chloroform aa ʒi (each one ounce), tincture capsicum, compound tincture cardamon, tincture of ginger aa ʒss (each half an ounce). M. S. Give in same dose as above.

A mixture of aromatic powder, gum arabic, and acetate of lead may be given after each evacuation.

The writer further stated that it was important to bear in mind that some preparation of opium or morphine, or morphine combined with chloral is the chief remedy for cholera, and the surest agent we can use to arrest the progress of the disease. When called, therefore, to a case already in the stage of invasion, morphine or morphine and chloral, should be administered hypodermically without delay, in order to get these sovereign remedies into the system as soon as possible. For, if we can arrest the disease before the patient has become collapsed, his chance of recovery will be greatly increased. Caution must be exercised, however, when this form of treatment is pursued, for narcotism is easily induced by repeated hy-

podermic injections, whereas very large doses of opiates can be given in this disease, by mouth and rectum, with comparative impunity. The strength of solution generally employed for injection is morphine gr. iiiss vel. gr. iv, with chloral hydrate ʒiiss vel. ʒiii, to the ounce of water. Inject 20 or 30 minims. The hypodermic use of morphine and chloral is, of course, contra-indicated when the stage of collapse has become developed. During this stage it is most essential that the patient be kept perfectly quiet, and in the horizontal position. No violent rubbings should be allowed; but the author has found it beneficial to gently rub the limbs and extremities with hot oil. To allay the thirst, let the patient suck ice frequently. Carbolie acid water, or simple acidulated effervescing drinks may also be given by the tablespoonful. It is unsafe to allow the patient to drink any fluid whatsoever in large quantities in this stage, especially when the acts of vomiting and purging have become less frequent, and the algid state well developed. Very small quantities of stimulants are useful, but they should be given with great caution, lest vomiting should be provoked. Stimulant enemata may also be given, but where the stomach has an inverted action it is often better to inject small quantities hypodermically. Experience teaches us that anything like the free use of stimulants in cholera is uncalled for and exceedingly harmful.

The reader had sometimes used small doses of atropine and strychnia, administered by hypodermic injection, apparently effectual in bringing about reaction. Amyl nitrite by inhalation may be given a trial, but it seems to exercise very little permanent or beneficial effect. Intravenous administration of milk and salines may be resorted to, but the reaction they induce is not generally of a permanent character. So that many of those who have given this method a fair trial have abandoned it. Of late years in Southern India, careful experiments have been carried out in reference to the value of impregnating the atmosphere of the sick-room with sulphurous acid by burning sulphur. The result has been, that this procedure has been introduced as part of the treatment of cholera. The writer has, on several occasions, tried this plan by subjecting the inmates of two different cholera sheds to exactly the same conditions and treatment in every respect, with the exception that in one the atmosphere of the shed was impregnated with sulphurous acid, and in the other this precaution was omitted. He found that the proportion of recoveries was considerably greater in the sheds where sulphur was used.

He therefore considers this an important adjuvant as part of the treatment. The atmosphere should not be so highly impregnated as to cause the patient or attendants to cough violently. Sulphurous acid thus applied is not only a useful remedy, but it is also believed to decrease the liability of the disease being propagated or contracted by the attendants. During the stage of reaction great care should be exercised, vomiting often continues, and the normal absorbing of the stomach and intestines is but slowly restored. Liquid nourishment by the spoonful should be most cautiously given, well salted broth, and milk given as hot as possible and not too frequently are the only

forms of food admissible until the enfeebled stomach shows signs of recovering its tone.

Peptonized beef tea and milk are frequently well borne if carefully prepared, so as not to nauseate the patient. If vomiting persists, the following emulsion may be given if deemed best:

R Acid carbolie gr. vii, bismuth sub. nit. ʒii, mucil acaciæ, aqua menthæ viridis, aa ʒi. M. S. A teaspoonful every hour or two.

But in this stage it is good treatment to let nature do the work of restoration, and give as little medicine as possible. We must bear in mind, however, that the kidneys must be assisted to resume their functions, and for this purpose mild diuretics, such as potass. nitrate, should be carefully administered. If fever supervenes, it is apt to be of a typhoid character. A combination of iodine and carbolie acid then exerts a beneficial effect. A popular formula is as follows:

R Acid carbolici.....gr. iiiss
Tincture iodine.....gtt. xv
Aq. menth piperitæ.....ʒiv

M. S. A tablespoonful every two or three hours.

To relieve restlessness and insomnia, potass. bromide is often useful.

The paper elicited much discussion as follows:

Dr. G. C. Paoli said the author of the paper had omitted to mention a prominent English physician, Marshall Hall, who a few years ago in London, read a paper which excited the interest of the medical fraternity of England, because he had advanced new ideas against the old or orthodox views, then prevalent; one item to his theory was, that in cases of cholera there is irritability of the vagus nerve, and on this theory hydrate of chloral and nitrite of amyl was administered to patients having the disease in the East Indies, but that the treatment in Europe was different. The speaker had seen four cholera epidemics from 1834 to 1866. And since the latter year he has treated the disease when the unwelcome visitor made its appearance in Chicago.

Regarding the treatment, he would add but a few words, for every physician by this time is well posted in this respect. Of all the remedies the best he had known was sugar of lead combined with opium, to check the diarrhoea, in the proportion of two grains of the former to one-fourth grain of the latter given in pill as the urgency of the case demands. In the stage of collapse it was useless to administer internal remedies, because the stomach would not absorb them. The blood is inspissated and would not flow, and the best application externally is dry warmth, in the shape of heated blankets applied so as to envelop the entire body and extremities. He did not believe in the bacillus or bacteria theory as a cause of the disease. No doubt they were present, but if so, they were innocent of the cause of the disease, for according to Darwin, perhaps we were once a bacillus—and surely we were innocent of intentionally causing cholera (laughter). Regarding an atom as being the cause—this he thinks is imaginary, for an atom is nothing that can be seen with the aid of a microscope. Dr. R. H. Engert asked the author of the paper what his percentage of recoveries were in the

cases which he had treated. Dr. John Bartlett gave his experience in treating 250 cases of cholera brought to a hospital in which he was attending physician. The per cent. of mortality was extraordinarily large. He expected he would be able to save one out of every two patients, but only one out of every six recovered, when they were brought to the hospital, they were in the blue stage, or semi-collapsed or partially cyanosed. Dr. J. H. Etheridge stated that he believed the nervous system would in the future be proven to have more to do with the ultimate pathology of cholera than bacilli, which he regarded as an illusionary aspect of the disease. Neurotic remedies should be given at first, and we will get at the gist of the trouble, which consists in the venous side being congested, and there is present vaso-motor spasm. To give opium, chloral, cannabis indicus and strychnia, will relax and tone this abdominal spasm of the nervous system, and aid the abdominal vessels to move correctly, perform their physiological action, and to prevent their pouring watery portions of the blood into the intestinal canal. Many years ago the theory was to start the bile, then give astringents. A few years ago Dr. Chapman, of London, in this disease, applied ice bags to the spine with very good success for diarrhoea, and to act on the abdominal vaso-motor nerves and aid them in the proper distribution of the blood. Medicines may also be given hypodermically. In the forties (1845-46) chloroform and ether were introduced as remedies on this theory of nerve spasm.

Regarding the bacillus that Dr. Koch has found in water tanks, and intestinal discharges of cholera patients, he is inclined to the same opinion as Dr. Paoli, so far as the cause of the disease is concerned, and further—the speaker regards them as a sort of “funny thing” in which one is amused by viewing them with a microscope. He illustrated his remarks by saying *that along in the sixties* Polli, of Milan, announced that he had discovered the true cause of quinsy. It being a germ or leucocyte, and in order to cure the tonsillitis, hyposulphite of soda should be administered to kill the germs. This theory of germs as a cause of quinsy being superlatively ridiculous, has long since been abandoned, and he, for one, is not yet convinced that bacillus is the cause of cholera.

Dr. R. E. Starkweather asked the author his views on the expediency of people retiring from the presence of the disease to remote or near distances? also what his observations have been as to frequency of cases of poisoning, where, for instance, a person having a grudge against a patient would try and make way with him by administering arsenic or strychnine to a sick person? He well remembered the year 1854, when the sentiment largely prevailed that people must retire from the disease if they wished to avoid getting it. He did not think this idea was as universally prevalent now. He was an advocate of cholera sheds, and that sheds ought to be erected for other pestilential diseases, for the public authorities to take care of the victims, and instanced how yellow fever had thus been treated at Pensacola with better success than by any other method. In a public point

of view, whether in the city or elsewhere, public authorities or health departments have a perfect legal right to do this, and could do so much better by having a number of well-trained nurses available than could be done by benevolent societies or organizations. For, in case of rice-water discharges, good nursing was the main thing to be relied upon.

Dr. D. O'Shea said he had been taught years ago that collapse in cholera was similar to shock from surgical injuries, and that the treatment in both cases should be similar. *Apropos* to the subject, he instanced the case of a tame rabbit which he was about to perform a painless physiological experiment upon, when the little animal became greatly alarmed at the surroundings. He remarked to those present that he believed the rabbit would die as a result of fright or shock, which it did in a few minutes, although it had, to all appearances, always been in good health; and as he did not remember reading anything on post-mortem appearances of the vessels of persons dying from fright or shock, he dissected the rabbit. No pathological appearance was present, except that the vena cava contained the blood of the body.

Dr. G. Newkirk asked if there was not some way by which the community could be educated, through the newspapers, so that the people could forestall these epidemics? Recently he had read in a Jewish newspaper that the Jews in France had not been afflicted with cholera. If this was true, he could not understand why they should escape its ravages, unless they had been instructed through Jewish papers to live better, or through their manner of dieting they had become insensible to the disease.

Dr. Scudder, in closing the debate, said first as to the per cent. of recoveries where the epidemic was severe, it was 20 or 30 per cent., or the percentage of deaths ranged from 80 to 90 per cent. where the epidemic was very severe. If the cases were seen early the fatality ranged from 40 to 50 per cent. In the sheds where cases were treated by fumes of sulphurous gas in the premises, nearly half the cases might be saved, whereas in one shed in the relief camp containing 20 cases, where exactly similar conditions were present where fumigation was omitted, 80 per cent. died.

In India the natives would not drink well-water. Their religion had much to do with the frequent visitations of cholera, for it taught them to drink only that which descended from heaven. The result was they drank surface water, or that which was stored in tanks near the temples of Lateran which they consider as sacred. In contrast to the natives of India were the Chinese and Japanese, because they drank well water and used the garbage and human offal to fructify the fields, and they were comparatively free from cholera. The Indians would not remove excrements and offal, neither did they cover it up, and when rain descended which amounted to 8 or 10 inches sometimes during a night, the water became polluted. The speaker did not see that any benefits would be derived by people running away from a district in which cholera was epidemic. General panic predisposes to the disease, and fright had much to do with its fatality. In India the poisoning of

persons afflicted with cholera by arsenic was frequent, and is largely undetected by the police. To warn the community, as one gentleman has alluded to, is an extensive topic. If the early known methods of checking it were resorted to, cholera would not become epidemic. The Indians are greatly prejudiced against European medicines, but (singularly enough), not so with European surgery, presumably because there are no native surgeons in India.

No European would travel without a bottle of camphor, and the English are always provided with a flask of brandy. The Europeans are well up in the use of preventive measures, and they would be sure also to be provided with chlorodyne, which is no longer a secret remedy.

LISTON H. MONTGOMERY, M.D., Sec'y.

Regular meeting August 18, 1884, D. A. K. Steele, M.D., President; and L. H. Montgomery, M.D., Secretary.

The first paper read was by Dr. P. C. Jensen, "On Cutaneous Therapeutics." After alluding to the histological and physiological relations of the skin and the internal secreting organs, including the mucous membranes, the writer discussed the question of cutaneous absorption, alluding to experiments in which limbs had been immersed in various solutions for weeks without any evidence of absorption. On the other hand, quoted Bichat as authority for saying that when the cutaneous surface of a limb is immersed in putrid gases, absorption takes place and the poison is subsequently eliminated by the bowels. He claimed that the rate and degree of absorption of any medicine depends largely upon its power of diffusion. Physiologically, he regarded the skin as a "colloid septum, on one side of which lie the blood-vessels containing an alkaline fluid, while an acid is on the other side; a condition most favorable for osmosis." He quoted Waller to show that alkaloïds dissolved in chloroform were readily absorbed from the cutaneous surface, while the same substances dissolved in alcohol were taken up very slowly or not at all. He then gave systematically the objects and methods of local treatment in diseases of the skin, including a considerable number of formulæ, but which we must omit for want of space.

Dr. C. W. Earle read a short paper on the Management of the Summer Diseases of Children, of which we can give only the following conclusions:

CONCLUSIONS.

1. The most frequent infantile disease in the city during the summer months is enterocolitis.
2. Excluding causes of infantile mortality largely beyond our control, improper feeding is one of the chief causes of the great number of deaths among this class.
3. Mothers should nurse their children. In lieu of this, a wet nurse should be procured. If this is impossible a mixed diet is preferable, and, lastly, artificial diet must be resorted to.
4. Artificial foods containing considerable caseine are found to be a cause of indigestion and summer diseases.

5. In many cases cows' milk diluted with water does not seem to agree with children. Barley water or rice water as the diluent seems to make a more physiological food.

6. Condensed milk seems to agree with a considerable number of children, but, in many cases, a sufficient quantity is not used to nourish a child. Used in proper quantities and diluted with rice or barley water, it is without doubt one of the best artificial foods.

7. Cream, mutton broth and white of egg are valuable adjuvants to the dietary of infants.

8. Whatever the artificial food a child is having, the physician should examine frequently for evidences that it is a proper food as regards quality and quantity. The normal elevation of the fontanelles and increasing weight are among the conditions denoting a satisfactory and favorable nutrition.

The remainder of the evening was spent in discussing the subject suggested by the paper of Dr. Earle.

FOREIGN CORRESPONDENCE.

PARIS LETTER.

PARIS, August 22, 1884.

The cholera epidemic, while decreasing at Toulon and Marseilles, has extended over the greater part of the littoral of the Mediterranean and even to the north of Italy, in spite of the disinfecting and quarantine measures carried out by the latter both by sea and land, but it does not make much progress toward the north. People must be chary as to how they receive news from the lay papers, particularly with regard to the prevailing epidemic diseases, as, intentionally or unintentionally, they do a great deal of mischief by exaggerating or even falsifying the real state of things. Thus it has been more than once reported that cholera was within the walls of Paris, and on each occasion it was proved to be false. Almost every sudden death that now takes place is put down to cholera, and there is no doubt that there have been errors of diagnosis even in the cholera-stricken districts, and the mortuary list from that disease is thus often unnecessarily swelled. The malady, however, seems to be dying out, and even the discussions at the Paris Academy of Medicine are wearing out without any satisfactory solution being arrived at as to the true nature of the present epidemic. It is now pretty generally admitted that the disease is of the genuine Asiatic type, though slightly modified, but Dr. Fauvel will not be shaken in his opinion, and still maintains that the cholera is of the sporadic type. You are aware of Dr. Koch's theory of the etiology of cholera, which he considers is due to the presence of bacilli in the intestines, but Drs. Strauss and Roux are not of the same opinion, and they do not consider that the pathological data furnished by Dr. Koch are sufficiently conclusive as to the nature or origin of cholera, as the bacilli described by the German savant as being peculiar to the disease were

found in other pathological conditions, such as in the stools of dysenteric patients, in the vaginal mucus of women suffering from leucorrhœa, and they were once observed in the uterine secretion of a woman affected with epithelioma of the cervix uteri. They report that in the epidemic in Egypt, they observed that the blood of cholera patients contained excessively small thin particles, presenting the aspect of organisms. At Toulon, the same phenomena were observed in the course of their researches, though not always. They suppose these corpuscles to be due to a special alteration of hæmoglobin, a view also shared by Dr. Malassez, who examined specimens of blood obtained from cholera patients in Egypt and Toulon.

It will be recollected that in the month of May last M. Pasteur announced his discovery of an attenuated virus of rabies. He at the same time requested the Minister of Public Instruction to appoint a commission to report on his experiments, of which commission M. Bouley was appointed President. On the 8th inst. M. Bouley's report appeared in the *Journal Officiel*. After giving an account of the results of the different methods of experiment adopted by M. Pasteur, viz.: 1, Trephining for inoculating the brain; 2, injection into the blood; 3, the bite of the dog, M. Bouley stated that the method by inoculation seemed to be the most efficacious, but yet it remained to be ascertained how long the immunity against hydrophobia would last—whether its influence would be persistent, or whether it would be so transitory that it would be necessary to repeat the inoculations frequently, which would render them *nil* in practice. Moreover, it was asked whether the preventive action of inoculation with the attenuated virus would be sufficient to annul that of the virus inoculated by the bite of a mad dog—in fine, whether man may obtain any advantage from “this great and memorable discovery.” In order to render the experiment by cerebral inoculation more intelligible, I may mention that the mode of procedure adopted by M. Pasteur was as follows: The matter for inoculation was taken from the pons varolii of a dog who died in the infirmary at Alfort from ordinary hydrophobia. A circular piece of bone five or six millimetres in diameter was removed with the trepan, and the inoculation was made with a syringe in which the extremity of the needles was bent almost to a right angle, so that the matter was inoculated immediately beneath the dura mater, and not into the cerebral substance. In this manner two dogs that had been submitted to prophylactic inoculation, and two which had not, as well as two unprotected rabbits, were inoculated. Subsequently two protected and two unprotected dogs were allowed to be bitten by a dog suffering from hydrophobia, and after the death of this dog, six other dogs, three protected and three unprotected, were inoculated.

On subsequent days, the experiments were repeated and varied. Altogether 42 dogs were used, of which 23 were protected by prophylactic inoculation, and 19 were unprotected. Of the 19 not protected, 14 died of hydrophobia; that is to say, of animals bitten, 3 out of 6 died; of 8 animals in whom intra-

venous inoculation was performed, 6 died, and all 5 inoculated through an aperture made in the cranium with a trepan; of the 23 dogs protected by prophylactic inoculation, not one died of hydrophobia, one died with diarrhœa; but inoculation showed that there was no reason to suppose that the animal had hydrophobia. M. Pasteur made the same statements before the International Medical Congress just held at Copenhagen, and M. Bouley, writing in the name of the commission, testified that, so far as the investigation had gone, it had been found that M. Pasteur had advanced no statement which was not rigorously exact.

At the banquet which closed the proceedings of the Congress at Copenhagen, M. Pasteur was placed to the right of the President, an honor due to his high and well won reputation.

Dr. Proust has been appointed Inspector General of the Sanitary Services of France, in the room of Dr. Fauvel, resigned.

Dr. Burg, whose name has been for nearly 30 years intimately connected with metallotherapy, particularly with reference to the influence of copper as a preventive of cholera, died last week in the 63d year of his age.

A. B.

COPENHAGEN, Aug. 18, 1884.

The British Medical Association and their annual dinner, and the International Medical Congress—the two great medical meetings of the year—are closed, and much has been accomplished by the interchange of views by the physicians from all parts of the world. The meeting at Belfast was unusually good, and the address of Dr. Cuming, the President, was both interesting and eloquent. The Sections were well attended, especially the one of Therapeutics, which held its first session at this meeting.

Drs. Sayre, Daly and Shoemaker, of the American Medical Association, read papers before several of the Sections, and reflected much credit upon their profession at home. The annual dinner attracted much attention, the short addresses being unusually good. I was very much struck by the toast to our guests, and as it referred to a prominent member of the American Medical Association, I will give you, briefly, Dr. Redfern's remarks, and the reply:

In proposing “the guests” Dr. Redfern said: “This is a proud day for Belfast, for Ireland, and for you, Mr. President, very specially. We have been honored with the presence of many of the most distinguished members of our profession who have come from great distances to take part in this meeting of the British Medical Association. I have always thought there is no profession or calling in life which combines so many sources of pleasure and enjoyment as the medical profession. I know of no satisfaction comparable to that which results from the relief of human suffering, and the prevention of disease; but when yesterday morning I witnessed what many of you also witnessed,—a little child, the victim of spinal curvature in the hands of one of our guests, Prof. Sayre, and saw its anxious, suffering expression changed to one of ease, comfort, and enjoyment, I

had no longer a mere intellectual conviction of the value of medical aid, but a real conviction of the heart.

"We all know that however careful and skilful a nurse may be, there is a wide difference between her handling of any injured part, and that of the surgeon whose firm and steady grasp gives confidence, checks vibration and affords instant relief. And such was the effect of the steady and gentle hand of our guest who sits near me, when the countenance of the little sufferer proclaimed its relief without the utterance of a word, and testified that the master's hand was upon the rope. I propose to you the toast of 'Our Guests,' and ask you to couple with it the name of Prof. Sayre, of New York, and Dr. Pozzi, of Paris."

Dr. Sayre rose to reply to the toast proposed by Dr. Redfern, and said, "Mr. President and gentlemen, I feel greatly honored at being called on to respond to this toast, but after the remarks of Dr. Redfern, I scarce know what to say, for when the heart is full the tongue finds it difficult to express the thoughts which throng the brain. I myself feel personally grateful to the members of the British Medical Association for the many kindnesses they have shown me both now, and on the former occasions when it has been my good fortune to be with you, and when told this afternoon that I was expected to respond to the toast of 'Our Foreign Guests,' I felt that if anyone had cause to be grateful for a kind reception, it was myself. I object, however, to the term 'foreign.' We all proud and happy to be your guests, but we Americans are not 'foreigners,' we have simply come back as chickens to the shelter of the old hen's wings. But if we do seem to you as strangers, the fault is not on our side, but lies with you yourselves. We send you our best men year after year, but I am sorry to say we look in vain for a corresponding representation of your body at our yearly national gathering. You remind me very much of what I heard a man say in your streets the other day; speaking of reciprocity, he said, 'reciprocity, what is that?' 'Ah, don't yer know, Pat; why it's wan of the grandest virtues on airth, it's wan of the noblest sentiments can govern a man. Why, it's gittin all you can and giving nothin' back in return.' We have our own Medical Association, and when I was here in 1879 I was so struck with the mode of formation of your body, and the influence exercised by your journal that I studied the matter very carefully, and made the establishment of a similar journal the subject of my address as President in the following year, and I am happy to say that my suggestions have resulted in the formation of the JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION, which is now in successful operation.

"We have, I must remind you, a way in our country of dividing the labor to be performed among different men, giving to each the part he is most fitted to perform. I represent the wheel-horse for hard work, but I see a short distance from me Dr. Shoemaker, of Philadelphia, who is for the leader of the team, all dash and fire, and I would recommend you all to his mercies."

Dr. John V. Shoemaker.

Mr. President and Gentlemen of the British Medical Association:—I deeply regret I cannot respond according to the prediction of our distinguished friend, Prof. Sayre. The American delegation, although very large, has been represented by the ex-President of the American Medical Association, Dr. Sayre, and no better and more eloquent member of our profession from America could have spoken to you upon this occasion. I see on all sides other representative men from my country. Here on my right is the venerable Dr. Moore, President of the American Surgical Society, and Dr. Didama, President of the New York State Medical Association; and on my left Dr. Daly, of the Medical Society of the State of Pennsylvania, gentlemen who could have addressed you much better than the youngest member of our delegation.

During the festivities this evening I have had mingled feeling of sadness and joy. Sadness to think that the great medical teacher and surgeon, the late Prof. Gross, of my country, who took so much pleasure in being present at your meetings and who always returned among us invigorated by his contact with you, who enthused the American physicians of the greatness of your organization, had but recently passed away while looking forward to meeting you all upon this occasion.

The feelings of joy have likewise been deeply experienced, that I should have the pleasure of being present at this meeting, and of seeing and hearing so many of the eminent English physicians whom we have heard so much about in America. The American physicians, and especially the delegates among you, are all most happy to see the great perfection that your organization has reached. It is to-day the most powerful society of medical men in the world, and your journal has well shown the large amount of scientific work you are doing every year. I might also add we are most happy to commend your journal, which is superior to any publication of the kind that comes to us from the four quarters of the globe. I speak not only as a physician, but as a journalist having opportunities of examining hundreds of medical periodicals, and I say to you that among them all the *British Medical Journal* has no equal. Your contributions, your editorials, and, in fact, the general make-up of your journal has no rival. As Dr. Sayre stated, and it was mainly through his suggestion, the American Medical Association have tried to follow your good example by also publishing our own journal. We are yet young in the work; the task is difficult, and we hope our efforts will be eventually successful. Come to America. I bid you all welcome on behalf of our delegates and the profession of my country. Let your numbers among our annual gatherings be larger. You will fill the older as well as the younger physicians with enthusiasm, and we may thus hope at least in time to approach to the great perfection of your journal and the British Medical Association.

The meeting of the Congress at Copenhagen was very large, the Germans, however, were greatly in the majority. The opening of the Congress on Sunday,

Aug. 10, in the presence of the King of Denmark and Greece and both royal families, was most impressive. The Danish people were most generous and hospitable toward all in attendance, especially to the large number of Americans. Very many of the foreign delegates present expect to visit America in 1887, at the next meeting, which already has the appearance of being very large.

DOMESTIC CORRESPONDENCE.

MEMBERSHIP IN THE NEBRASKA STATE MEDICAL SOCIETY.

ASHLAND, NEB., Sept. 3, 1884.

N. S. DAVIS, M.D., EDITOR.

Dear Doctor:—You will oblige me very much if you will insert these lines into your next issue of the JOURNAL, as well as the subjoint resolution, adopted by the Nebraska State Medical Society at its last session, May 14 and 15.

MINIMAL QUALIFICATIONS FOR MEMBERSHIP IN THE NEBRASKA STATE MEDICAL SOCIETY.

No applicant for membership in the Nebraska State Medical Society shall be received, who is not a graduate of a school the requirements of which embody the following conditions:

1. Creditable certificate of good moral character.
2. Diploma of graduation from a good literary and scientific college or high school; or, lacking this,
3. A thorough examination in the branches of a good English education, including mathematics, English composition and elementary physics or natural philosophy.
4. Branches of medical science to be included in the course of instruction: Anatomy, physiology, chemistry, materia medica and therapeutics, theory and practice of medicine, *pathology*, surgery, obstetrics, gynecology, and *medical jurisprudence*.
5. The time occupied in the regular courses or sessions from which students are graduated shall not be less than five months, or twenty weeks.
6. Two full courses of lectures not within one and the same year of time shall be required for graduation with the degree of Doctor of Medicine.
7. Regular attendance during the entire lecture courses shall be required, allowance being made only for absences occasioned by the student's sickness, such absences not to exceed twenty per centum of the course.
8. Regular examinations or quizzes to be made by each lecturer or professor daily, or at least twice each week.
10. Each student shall have dissected during two courses.
11. Attendance during at least two terms of clinical hospital instruction shall be required.
12. Time of professional studies before graduation shall not be less than three full years, including the time spent with a preceptor, attendance upon lectures or at clinics and hospitals.

13. The college must show that it has a sufficient and competent corps of instructors and the necessary facilities for teaching, dissections, clinics, etc.

A. S. v. MANSFELDE, M.D.

Permanent Secretary Neb. State Medical Society, Ashland, Neb.

My reasons for thus troubling you for space are: The absence of a professorship on *General Pathology* in most all the annual catalogues of colleges finding their way to my table, especially those of Illinois, the State Board of Health of which has adopted the self-same resolutions for its guidance; in fact, those of the Nebraska State Medical Society are copied from them.

Now, two conclusions are self-evident. 1. Colleges which do not pay attention to these resolutions, *i. e.*, do not have 10 professorships as above indicated (and spicing in of General Pathology in the Chair of Principles and Practice of Medicine is not to be thought of, as far as the Nebraska State Medical Society is concerned) cannot expect their graduates to receive recognition, *a*, by the Illinois State Board of Health, and *b*, by the Nebraska State Medical Society.

2. The resolutions above referred to are, as so many other good resolutions, the pavement of the road to hades.

Speaking for the Nebraska State Medical Society and not as one of its officers, but as one of its members, who thinks himself capable to voice the society's feeling in this matter, I can avow that no graduate of any college which does not fulfill the above resolutions to the letter, need expect recognition as long as those resolutions are in force. Let students and teachers take notice of this!

But what about the Illinois Board of Health? We, out here in our young State, feel a little strange when we notice that the Illinois colleges pay no attention to the resolutions of their State Board, excepting the Chicago Medical College, perhaps. How is this?

An explanation would please the many readers of the Association's journal in Nebraska very much, and is respectfully solicited, with or without the aid of Dr. J. H. Rauch.

Very truly yours,

A. S. v. MANSFELDE.

PARASITES.

While physicians are diligently searching, in this latter day, for all sorts of micro-organisms, whether as tubercle bacilli, cholera bacilli, pneumonia micrococci, or what not, there is another form of creature demanding vigorous antiseptic treatment. Though not microscopic of body, it is infinitesimal of soul. We do not need to hunt for it with magnifying lenses, nor to immerse it in staining fluids. In its own natural color, that of unblushing effrontery, it daily makes itself apparent to the eye of the medical man, and, we may add, that of his collector. Do we need to describe this pestiferous vermin further? It is that most odious of all parasites, who feeds on the tender heart of the doctor.

Seriously, why should the medical man be compelled to suffer at the hands of "dead-beats" in a manner and to a degree that would be tolerated by

no other professional or business man? The medical profession does an enormous amount of charitable work, publicly and privately. Its services at dispensaries and hospitals are purely gratuitous, and in addition to all this there are few medical practitioners who do not attend clients in limited circumstances, either gratuitously or for an insignificant remuneration. Yet these public benefactors are daily imposed upon by worthless scamps, who employ every means possible of beating the doctor out of his justly-earned fees. It is proverbial that the doctor's bill is the last to be paid, even by those who have no intention of evading it ultimately. Furthermore, the medical man is expected to give credit to persons whom a merchant would never think of trusting. It is mean and uncourteous for him to present his bill under several months, and, if he insists on the payment of it, he is reviled. Now, why should these things be? The average practitioner of medicine, even if he do not enter the profession for the sole purpose of earning a livelihood (and if such be his motives he had better look elsewhere), is, nevertheless, compelled to support his family by his practice. If so, then, why should he not conduct it on strictly business principles, having due regard, of course, to professional ethics and those moral considerations that should actuate the honest, high-minded gentleman. Above all, why should he be forced to attend patients who have no intention of remunerating him? If people be really impecunious, let them go to the dispensaries, and if they are "dead-beats" let them be published as such. Can there not be a black list prepared, to which all physicians can have access? So soon as a doctor is defrauded of his fee by one of these parasites, he might publish the name and address in some local journal with which arrangements had been made to have space allotted to such a black list. We feel convinced that if physicians would form some such plan for mutual protection, the evil of which we complain would be greatly lessened. This is but a suggestion, and we trust some philanthropic mind will concoct an effective parasiticide of the kind required.

R. H. B.

NECROLOGY.

TYLER, GRAFTON, M.D., of Georgetown, D. C., was born in Prince George Co., Md., Nov. 21, 1811; died at his residence, corner Washington and Gay Sts., Aug. 26, 1884. He is descended from a family of Tylers who came from England and settled in Maryland in 1660.

The doctor was the second son of Grafton and Ann H. (Plummer) Tyler, and was born on the ancestral estate. The late Prof. Samuel Tyler, of the Law Department of Columbia College, was an older brother. Dr. John Tyler, of Frederick, Maryland, was an uncle of his father, a physician of note in his day; was a fellow student of the celebrated Abernethy in London and Edinburgh. Dr. Wm. B. Tyler was his son, and fully sustained the reputation of his father in Western

Maryland. Dr. Grafton Tyler received a good classical education at Rev. James Carnochan and Rev. James McVean's school in Georgetown before the former became President of Princeton College, N. J.

Dr. Tyler began the study of medicine with Dr. Richard Duckett, a physician of ability and large practice, who lived on the adjoining plantation to Dr. Tyler's father.

Dr. Tyler attended lectures at the University of Maryland, and became an office student during the winters with Prof. Samuel Baker, Sr., of Baltimore.

Dr. Tyler received his medical degree from the University of Maryland in 1833. On leaving college, his preceptor was so attached to his pupil that he at once took him into partnership, though each retained their separate residence. Early in his professional life he had a predilection in favor of surgery, and did some good work in that department. But he gradually gave that up, and devoted himself almost exclusively to general family practice and consultations with brother physicians.

The labor of a large country practice told so seriously upon his health that, by the advice of physicians, he gave up professional business, which was beyond his physical powers to discharge. In 1843, he removed to his late residence in Georgetown, where the labor would be less than in his former field of duty. He speedily acquired a good practice, and shortly after settling here he was selected as Physician to Georgetown College, a position in which he gave eminent satisfaction, and retained to the time of his death.

In 1846, Dr. Tyler was elected to the Chair of Pathology and Practice in the Medical Department of Columbia University, and a few years later of Clinical Medicine in the Washington Infirmary. His duties to a large clientage induced him to resign these positions in 1859, but he was elected to and retained the position of Emeritus Professor. He was appointed a member of the first Board of Visitors of the Government Hospital for the Insane, but after six years' faithful service resigned.

The active temperament of the doctor and his popularity with the people of Georgetown led him to be elected to the Council of Corporation of Georgetown, and was made President of the Board.

He was also for years President of the Board of Health of Georgetown. Dr. Tyler early identified himself with medical organizations, becoming a member of the Medico-Chirurgical Faculty of Maryland in 1833. He was a member of the Medical Society of the District of Columbia since 1846, and served in all its offices, including that of president in 1872. He was also a member of the Medical Association of the District since 1848, and has held most of its offices. He became a member of the American Medical Association in 1848 and attended meetings in 1852 and 1855, when he was elected one of the vice-presidents. He also attended in 1858-'66-'68-'70-'72, and 1884.

He was one of the consulting physicians of Providence Hospital and president of its medical board from its opening in 1863. He was one of the original incorporators and a director of the Children's

Hospital since its organization. Dr. Tyler was a ready writer, a fluent and eloquent public speaker, and was selected by the physicians on several occasions to deliver public addresses, some of which have been published. He also found time to contribute valuable articles to medical journals. An article in 1841, contributed to the *Baltimore Medical and Surgical Journal*, on an obstetric subject attracted a good deal of attention. An address on "Medicine as a Science and an Art," in 1851, delivered in the hall of the Smithsonian Institution, was also an able paper. This was printed in pamphlet form. Dr. Tyler has been through life an exemplary member of the Protestant Episcopal Church. In January, 1836, he was married to Mary M., daughter of Walter Bowie, Esq., of Prince George's Co., Md.

He had eight children, five sons and three daughters. One of his sons, Bowie Tyler, is a physician in full practice in Georgetown. Dr. Tyler was a man of polished manners and great kindness of heart, and was extensively employed in times past by our leading citizens as well as by statesmen sojourning in Washington city. Dr. Tyler will be greatly missed by numerous patrons and strongly attached friends, both in Washington and Georgetown. He leaves but six physicians living who were in practice in the District when he settled here, namely, Drs. Lindsly, Burrows, Liebermann, Howard, May and Ritchey.

The Medical Society of the District of Columbia held a special meeting on the evening of the 27th inst., and passed a series of resolutions expressive of their regard for the memory of Dr. Tyler, and resolved to attend his funeral in a body.

Doctor Tyler's remains will be interred on Friday 29th inst., in Oak Hill Cemetery, by the side of his wife, who died some years ago.

J. M. T.

MISCELLANEOUS.

A QUEER SIBERIAN DISEASE.—The person affected seems compelled to imitate anything he hears or sees, and an interesting account is given of a steward who was reduced to a state of perfect misery by his inability to avoid imitating everything he heard and saw. One day the captain of the steamer, running up to him, suddenly clapping his hands at the same time, accidentally slipped and fell hard on the deck. Without having been touched the steward instantly clapped his hands and shouted; then, in helpless imitation, he, too, fell as hard, and almost precisely in the same manner and position as the captain. This disease has been met with in Java, where it is known as "Lata." In the case of a female servant who had the same irresistible tendency to imitate her mistress, the latter, one day at dessert, wishing to exhibit this peculiarity, and catching the woman's eye, suddenly reached across the table, and seizing a large French plum, made pretense to swallow it whole. The woman rushed at the dish and put a plum in her mouth, and after severe choking and semi-asphyxia, succeeded in swallowing it; but her mistress never tried the experiment again.—*London Medical Record*.

OFFICIAL NOTICE.

ANNUAL DUES from members of the Association—*Five Dollars* per annum—are payable directly to the Treasurer. Such payment entitles them to receive the JOURNAL of the Association for one year.

SUBSCRIPTIONS TO THE JOURNAL from those who are not members should be forwarded to the office of publication, Chicago.

BACK VOLUMES OF THE TRANSACTIONS may be procured, at reduced rates, by addressing the Treasurer.

THE INDEX to the 33 Volumes of Transactions will be forwarded, postpaid, on receipt of *One Dollar* by the Treasurer.

According to a resolution passed May 9, 1884, at the Washington meeting, continuous payment of Annual Dues is required, to retain permanent membership.

RICHARD J. DUNGLISON, M.D.,

Treasurer.

Lock Box 1274, Philadelphia, Pa.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT UNITED STATES ARMY, FROM AUGUST 31, 1884, TO SEPTEMBER 5, 1884.

Byrne, Charles C., Major and Surgeon. Relieved from duty in Department of California and to report in person to the Com'd'g General Dept of the Platte for assignment to duty. (S. O. 207, A. G. O., Sept. 3, 1884.)

Town, F. L., Major and Surgeon. Relieved from duty in Dept. of the Columbia and to report in person to the Com'd'g General Dept. of Texas for assignment to duty. (S. O. 107, C. S., A. G. O.) Granted leave of absence for twenty-five days. S. O. 127, Dept. of the Columbia, Aug. 25, 1884.

Havard, Valery, Capt. and Asst.-Surgeon. Relieved from duty in Dept. of Texas and to report in person to the Com'd'g General Dept. of the East for assignment to duty. (S. O. 207, C. S., A. G. O.)

Hall, Wm. R., Capt. and Asst.-Surgeon. Relieved from duty in Dept. of Texas, and to report in person on Oct. 1, 1884, to the Superintendent general recruiting service in New York City, for duty at David's Island, N. Y., relieving Asst.-Surgeon M. E. Taylor, from duty at that station. (S. O. 207, C. S., A. G. O.)

Gibson, R. J., First-Lieut. and Asst.-Surgeon. Relieved from duty in Dept. of the Missouri, and ordered to Dept. of California for duty. (S. O. 202, A. G. O., Aug. 28, 1884.)

Hopkins, Wm. E., First-Lieut. and Asst.-Surgeon. The leave of absence granted him in S. O. 67, Aug. 7, 1884, Dept. of Arizona, is extended one month. (S. O. 204, A. G. O., Aug. 30, 1884.)

Dietz, Wm. D., First-Lieut. and Asst.-Surgeon. Relieved from duty at the Mil. Academy, West Point, N. Y., and ordered to the Dept. of the Missouri for duty. (S. O. 202 A. G. O., Aug. 28, 1884.)

LIST OF OFFICIAL CHANGES IN THE MEDICAL CORPS OF THE NAVY, FOR THE WEEK ENDING SEPTEMBER 6, 1884.

P. A. Surgeon P. M. Rixey, from special duty at Washington, D. C., September 8, and to the "Lancaster," European squadron.

Surgeon A. S. Oberly, from the "Richmond," August 30, and wait orders.

P. A. Surgeon S. H. Dickson, from Asiatic squadron July 29; sick leave August 30, 1884.

PUERPERAL PYÆMIA.

BY WM. H. MYERS, M.D., FORT WAYNE, IND.

[Read before the Indiana State Medical Society, June 11, 1884.]

It is within ten or fifteen years only that much has been done to entitle medicine to a place among the exact sciences. Up to this period we knew disease only by groups of effects; of their causes we had no certain knowledge; we dealt only with the symptoms.

As the methods of research adopted became stricter and more systematic, we have been enabled to look forward with much certainty and to offer speedy solutions of many problems hitherto deemed inscrutable, and the men of science in medicine anticipate with much hope the possibility of triumph, not merely over individual cases, but over whole genera of disease.

I have, therefore, thought I could not choose a more opportune theme than pyæmia, with its closely allied diseases, and to refer briefly to the light cast by recent discoveries upon its nature and treatment in puerperal cases.

"Pyæmia," in the language of Déspine, "is purulent absorption." As septic absorption may be confounded at the bedside with the pyæmic process, we are at once compelled to define the distinctive characteristics of each.

To Burdon-Sanderson we are indebted for the following clear definition of pyæmia:

"It is a process which has a beginning and a termination of a definite kind, a center of origin, lines of diffusion, and secondary results. It is developed and goes on and on to its fatal end."

Septicæmia has no necessary connection with any local process. It is, therefore, not developed, but is a constitutional disorder of limited duration, produced by the entrance into the blood-stream of a certain quality of septic material.

You will apprehend from the foregoing, that I do not use the terms pyæmia and septicæmia as convertible. I believe that a sharp line of definition between these two conditions exists.

You cannot have pyæmia without pus, and you cannot have pus without inflammation, as pus is one of the products of inflammatory action, and whether

its absorption be from an abscess, an open wound or a solution of continuity of the uterine surface or its appendages, it results in the pyæmic processes.

With Jonathan Hutchinson, pyæmia, I hold, is produced by an inflammation of the patient's own tissues.

But I imagine some may controvert the opinions here expressed, by referring to Waller, Cohnheim, Virchow and others, who state that pus is nothing but a white blood globule, strayed outside of a capillary vessel, and that no property or power can with certainty be ascribed to the white blood-cell but which is certainly predicable of the pus-cell.

As anatomical elements they offer no points of distinction. Their chemistry is the same. To both is accorded the property of growth and multiplication by subdivision. Neither of them contribute to the formation of any higher structure. Neither of them eventuate in anything different from cells; as Beale would say, "masses of germinal matter, but as such live, die and disintegrate." Whilst the presence of pus may be considered as the approximate cause of the pyæmic processes, yet it alone, as such, cannot produce all of the symptoms present in pyæmia. The exciting cause of pyæmia has been a matter of dispute for hundreds of years, but that the antiseptic treatment has almost driven pyæmia from the hospital wards is a matter of fact, and that its disappearance, coincident with the introduction of Listerism in surgery and obstetrics, leads us to hope that a solution of this hitherto unexplained question as to its origin is not far distant, and that probably the statement of Burdon-Sanderson, that "pyæmia originates by the introduction into the living tissues and eventually into the blood, of a poison which is itself a product of inflammation"; and that the metastatic abscesses are characterized by the presence of bacteria, may be regarded as the solution.

A predisposing cause in disease may be defined as a cause which, whilst not producing disease itself, renders more effective the exciting cause; and under this head we must include the environment of the patient, shock, loss of blood and depression of the vital powers. For instance, if you take a large series of cases of patients who have lost great quantities of blood, or are debilitated, or greatly depressed, many of them will be the victims of pyæmia. Historic mention of this is made by military surgeons. It was so in the Crimea and in the French campaign. In our own Rebellion the Confederate soldiers suffered more after their defeats. In the Franco-Prussian war pyæmia was less prevalent in the German army, they

being the victors, than in the French, they being the vanquished.

Let me now direct your attention to puerperal pyæmia, and the evidence that any morally as well as physically depressing cause is discovered to coöperate in the same way. Dr. Newman, in discussing puerperal pyæmia, uses the following language in speaking of the predisposing causes above referred to: "These do unquestionably seem to me to play a material part, at all events, in predisposing the system to the virulent development of these poisons however they happen to be introduced."

Hicks says: "There is another point which cannot be left out of consideration, viz.: that violent mental emotions also are followed by symptoms precisely similar to those which followed zymotic influences or the existence of putrid discharges."

The puerperal condition itself may be considered as a predisposing cause, and is so referred to by the ablest writers.

If we look at what a lying-in woman is, we see there a peculiar constitution ready to receive poison and ready for those poisons to ferment, and so on to a disastrous issue.

Richardson in speaking of this condition of the woman after delivery says, that she is in a nervous condition supplying from her own potential energy the movements of the foetus. Then there are cases where there has been some local injury, exposure of cellular tissue, the rupture or exposure of a vein, the formation of a modified secretion, the absorption of that and death from what Mr. Hutchinson correctly calls poisoning immediately from the patient herself.

Grailly Hewitt thus graphically describes the condition of a woman immediately after parturition, as a predisposing cause of pyæmia: "The woman has a large bleeding for instance, at the time of childbirth; the contractile power of the uterus fails to a certain extent, the expulsion of the debris ceases, and it is taken up into the circulation, and I explain in this way those cases in which the scarlet fever poison and other fever poisons apparently produce disease. They destroy the vitality of the patient to a certain extent; they take away the safeguard; they abolish the contraction of the uterus and they produce paralysis of the organ for the time being and the pyæmic process immediately takes possession of the uterine sinuses."

Let me here direct your attention to the fact that these cases are often auto-genetic; that the woman is herself the factor, and subsequently the recipient of the poison generated "*in utero*" which is received into the lymphatics, the veins, the peritoneum, and into the body generally. In this morbid uterine condition, usually the result of hæmorrhage, followed by a loss of vitality and contractile power, I would grasp the soft, spongy, uncontracted uterus with my hands, compress it, thereby expelling clots; afterwards wash out putrid or putrescent discharges of the womb and vagina, by means of Higgins' syringe, Condy's Fluid and warm water with carbolic acid, until the lochia became quite inodorous; this operation I would repeat

every two hours if the temperature should reach 102° Fah.

Now let us pause here a moment. For in every professional life in medicine there are times and events well calculated to *cause* us to pause and sometimes review the line of treatment suggested by even the most advanced therapeutists and clinicians; and we are often compelled to express strong doubts amid disappointments. These mental states are thrust upon us, and we reconsider carefully the factors, thus profoundly impressing us, either by disaster or unexpected recovery.

Professor A. S. Ranney, speaking upon this subject with its attendant disappointments, says, "It brings up recollections of frustrated hopes, of untimely graves, of surgical skill carefully exercised, but of no avail."

Professor Krakowizer also says:

"It is bad enough that the surgeon, the obstetrician, find inherent difficulties in the treatment of wounds and in the management of abnormal labor; that they cannot help sometimes making mistakes, in choosing the time for operations and in performing them, but it is discouraging to have to take an element into calculation in performing one's professional duty, that neither lies in the nature of the case nor can be warded off by any degree of scientific acumen or skill."

These reflections of my own and of the authorities just quoted, have been profoundly impressed upon my mind by the following case:

On the 24th day of December, 1883, Mrs. E., æt. 30, was one of the passengers in a railway car, as it was on a crossing a rapidly advancing locomotive struck the car with great violence; overturning it. She was thrown against the seat and sides of the coach; upon my arrival, I found Mrs. E. laboring under shock, mental and physical, the latter the result of numerous cuts about the head, and abdominal bruises. At the time of the accident she was *enciente* six months; she was conveyed to her home, a distance of one mile, and properly placed in bed, where she remained for nearly two weeks, during which time she had a slight uterine hæmorrhage for the first few days, and during the remaining time was strongly threatened with premature labor, but this was averted by quiet and strict horizontality. During the remaining period of her term, she always complained of pain over the right lumbar region. Her confinement occurred March 13, 1884.

Nothing unusual occurred in the first and second stages of labor, only they were more protracted than in her two previous labors, in which I attended her. The protraction seemed to be owing to the failure of nervous power. In the third, the stage of expulsion of the placenta, (and this itself may be divided into three different periods, first, detachment from the internal surface of the uterus; second, expulsion into the vagina, and third, protrusion externally), after waiting the usual time, and finding that the diminution of the womb did not occur as is usual in this stage, I was apprehensive that the placenta was adherent to the surface of the uterus.

During the interim usually allowed, between the

birth of the child and the placental delivery—fifteen or twenty minutes—a severe hæmorrhage ensued, and this determined my prompt interference to aid in the expulsion of the placenta, first by Crede's method; failing in this and fearing the further loss of blood, I proceeded to deliver by following up the cord, and found my apprehensions verified, that the placenta was adherent. It was firmly attached at its lower edge to the uterine wall.

Pressing firmly with my left hand externally over the fundus uteri, I carried the fingers of my right hand between the placenta and the internal surface of the uterus, and thus destroyed the adhesions and liberated the placenta without force and with the greatest possible care. Its expulsion now followed. No laceration of the cervix or perinæum was detected, and I do not believe any existed. After being properly put in bed, fluid extract of ergot was administered in large doses every hour, to prevent hæmorrhage by promoting uterine contractions. I was informed the next morning that several clots had been expelled during the night, and that she had remained free from any urinary distress. I entertained grave fears for my patient, fearing that the pyæmic process would be set up in that portion of the placental site where the adhesions had been broken up, and also that the nervous prostration from previous shock and the loss of blood occurring in the third stage of her labor, would act as powerful predisposing causes. Under these impressions, I strictly observed every antiseptic precaution, from the first of her labor.

A healthy male child was born on the 13th, as previously stated. She progressed favorably until the 21st (eight days), when at 1 P. M. a messenger informed me that she had a most violent rigor, with profuse perspiration. Being at the time ill, I was unable to respond to the call, and Dr. H. V. Sweringen was called, and reported that the temperature was 106°, that five hours afterward the temperature was 101°. Now followed in succession, usually twice in twenty-four hours, rigors, profuse perspiration, sharp elevated temperature, varying from 105° to 100°, during the remaining days of her illness. It was now believed by us to be a well-pronounced case of pyæmia, and we adopted the treatment suggested by our best clinicians. That this was a case of auto-genetic pyæmia was evident from the history of the case, using the term auto-genetic "self," "I generate," and applying it in diseased conditions in the same sense as originally used by Owen in anatomy, elements developed from distinct centres. In biology, development refers to an unfolding, and refers to the organic changes which occur in a living germ.

I have already expressed my own belief that the presence of pus alone did not establish the pyæmic process, but that there was something special in the state of the patient's health which led to the disastrous result; the previous shock which she sustained, and from which she had not recovered at the time of her accouchement, the loss of blood at that time, and the adherent placenta were the fatal factors that invited blood-poisoning.

Cheyne in his *Antiseptic Surgery* teaches us that the following conclusions were forced upon him by

the results of numerous experiments; that the blood and tissues of healthy living animals do not contain organisms or their spores, and have no inherent tendency to undergo fermentation.

LIFE IS THE GREAT ANTISEPTIC!

Preserve it, restore healthy functions, control by rest and position, the nervous vascular and muscular action, and the repair of injuries proceeds like healthy nutrition. Life and putrefaction are not correlative but antagonistic, and in proportion as we utilize and economize the attributes of life we will find ourselves independent of those changes which are inherent to decomposing organic matter. Lister suggests that the tissues of a healthy living body have a power of counteracting the energies of bacteria in their vicinity and preventing their development. Specific diseases are like specific forms of animal or vegetable life; they can be produced only by specific preëxisting germs. There is no such thing as spontaneous generation of the entities which generate disease any more than there is of the innumerable forms of animal life which make their appearance wherever a material suitable for their development is exposed to the atmosphere. We know that the air is full of floating living particles, ready to spring into activity whenever they may light upon a congenial soil. In such numbers do they exist that present but the proper soil, and the appropriate germ inevitably finds its way to it. Each particular malady is due then to the invasion of the system by some microscopic organism, which multiplying itself within the living body, gives rise to the phenomena which physicians describe as the disease. This is the teaching of McLagan in his *Germ Theory of Disease*. This is true also of certain diseased conditions, as in the case of wounds. It is now believed that when they are other than normal that it is owing to the invasion from without of living organisms, and that the constitutional disturbances previously regarded as the natural consequence of every severe wound or surgical operation were really dependent on the introduction of air-carried germs, of living organisms into them, and that in their absence, healing by the first intention is certain to occur. But we are told by those who doubt Listerism, that if there be any truth in the theory, these air-born germs should settle and multiply themselves in every cut or solution of continuity and that the danger from the most trifling incisions should be as great as it is from the most serious. To this we reply, by presenting a most important fact in connection with the micro-organisms to which these germs give rise without which the higher forms of animals which they infest must speedily succumb before their attacks. If their invasion is undertaken in insufficient force, or upon an animal in robust health, they are refused a foothold and expelled, or if they have secured a lodgment in the tissues they are laid hold of and digested by them; this fact has been repeatedly observed and demonstrated by Cameron, Lister, Billroth and Cheyne. They have also proved by experiment that an undisturbed healthy coagulum in the vicinity of living tissues will resist the development of putrefactive bacteria even when present in a highly

concentrated form. In illustration let us apply these statements or facts to surgical procedures and they will explain the success which has attended important operations without antiseptic precautions, notably does this apply to ovariectomy.

In 1874, I removed an ovarian tumor from a patient *æt.* 36 years. The tumor weighed 45 pounds. From my notes of the case, I read that the rebound to health was rapid and complete. This may be attributed partially to the preparatory treatment and the complete isolation of the patient with absolute rest. No antiseptic precautions were used except cleanliness. In this case I now believe the recovery was largely due to the high vital energy of the peritoneal surface. We all know how rapidly a wound in the peritonæum may heal or the rapid peopling of the lymph in the wound with vigorous new living elements; for the formation of lymph proceeds more rapidly in proportion as the wounded tissues are in a more vigorous condition. Hence, the power of organizing blood-clot or lymph to resist the development of putrefactive bacteria. This high vital endowment of the peritonæum is of wide application in abdominal surgery, and explains the remarkable success of Lawson Tait—three deaths in his last 50 cases without the use of carbolic acid—and the same remark may be applied to Professor Keith, of Edinburgh.

Primary union or union by the first intention, can then only occur in a healthy wound, and the phenomenon of union in this manner is explained by the resisting power of the tissues preventing the development of putrefactive bacteria.

Dr. Antonine Magnin, in his work on Bacteria—page 443—in chapter on “Bacteria in Surgical Lesions,” says: “The blood and tissues of healthy persons do not, under ordinary circumstances, contain bacterial organisms,” and that “putrefactive decomposition of organic fluids is due to bacterial organisms.” This doctrine is also sustained by Watson Cheyne in the following language: “The blood and tissues when in a healthy state have the power, of themselves, of destroying organisms when these are introduced into the body.”

In discussing the destroying action of the healthy living tissues on bacteria he particularly refers to perfect mechanical rest, and by attention to the general health, stating when the tissues are in perfect health and the clot is undisturbed, and when kept in such a state they resist the development of organisms without any antiseptic appliance, and the wounds heal frequently by first intention. He asks the question, “How is it that union by the first intention can occur when during the operation organisms enter the wound, both as dust from the air, also from the water in which the sponges are soaked, when there is also between the cut surfaces a layer of blood or lymph; how is it that blood does not putrefy between the cut surfaces of a wound?” He answers these questions by quoting the following forcible arguments from Lister, who says: “The fact is, that a thin layer of blood, although containing numerous causes of putrefaction, does not, as a rule, putrefy if it be placed between two healthy living cut surfaces.”

Or, to state the fact in another way, “these organisms, which are certainly present, cannot develop in a thin layer of blood or lymph placed between two healthy living freshly cut surfaces;” or, again, “the living tissues when in a healthy state have the power of preventing the development of organisms in their immediate vicinity.

Watson Cheyne, in his valuable work on Antiseptic Surgery, again says that “he has demonstrated that if into a *healthy* living animal a small quantity of ordinary bacterial fluid be injected, the bacteria lose their vitality and disappear; also, that organisms cannot be found in the living healthy body, unless a considerable amount of their products be introduced along with them.” On the other hand, he has demonstrated how, if the animal were out of health, organisms could live in the blood and tissues much more easily. The same is the case in union by the first intention. If the part be of high vital power, and in a healthy state, and if there be an extremely small quantity of blood between the cut surfaces, union by first intention will almost certainly occur. If the part become inflamed, or if the patient be in a weak state of health, union by first intention, without aseptic means, becomes a matter of great uncertainty.

Cheyne states that Traube and Gscheidlen have found that blood taken with precaution from a healthy living rabbit, into which twenty-four or forty-eight hours previously $1\frac{1}{2}$ c. cm. of bacterial fluid had been injected, could be kept for months without undergoing putrefaction. He adds: “The facts that the blood and tissues of healthy living animals do not contain living organisms, show sufficiently that they have the power of destroying them, for otherwise there are frequent opportunities for the entrance of these into the circulation.”

That one of the factors predisposing to pyæmia in Mrs. E.'s case was the adherent placenta, mental perturbation, hæmorrhage with shock, we can no longer doubt, from the light thrown upon bacterial development as not occurring in healthy living tissue, and we pass to the consideration of the adherent placenta in her case. Why was it adherent? That this adhesion is unusual, rarely met with by the most experienced in our profession, will be admitted; but as it did occur, to what is it attributable? Drs. Rhamsbotham, Burns, Davis, Ingleby and Hamilton attribute it to the presence of lymph thrown out as a product of inflammatory action, and that the inflammation is usually excited by falls, blows or injury received during gestation, and advance in support of this theory that in the lower classes it is much more frequent than in the higher circles, this being due to their greater liability to accident.

Is it possible to remove entirely the adherent portions of the placenta?

So strongly specialized is the fatality following this adhesion that I unhesitatingly answer the question in the negative. The exceptions being a mere trace in medical literature.

Sir J. Y. Simpson in speaking of the adherent placenta says: “In some instances the organic union between them is so firm and the corresponding sur-

face of the uterus and placenta are so intimately blended together that the uterine contractions are altogether inadequate to break up the morbid organic connection existing between them, and occasionally it has been found impossible to disunite them completely from one another by any manual efforts during life or even by dissection after death."

Playfair, speaking of the treatment of adherent placenta, says: "The removal is always a delicate and anxious operation, which, however carefully performed, must of necessity expose the patient to the risk of injury to the uterine structures, and of leaving behind portions of placental tissues." He also says that "the retained portions may decompose, give rise to foetid discharge and septic infection," and that, "such cases must be treated by antiseptic intra-uterine injections."

Meadows advises "that if the adhesion be so intimate that considerable force is necessary for separating it, it is far better to leave a portion adherent, and in such a case the vagina, and even the uterus should be washed out frequently with disinfecting fluids, such as Condy's solution."

Hamilton, in his *Outlines*, says of the adherent placenta: "Of all the cases of retention this is the most difficult and dangerous; the case is intricate and perplexing."

Denman, in speaking of the placental adhesion to the uterine wall says: "A perfect separation will be extremely difficult and sometimes impossible."

Similar views are entertained by Chailly, Burns, Davis, and Rodney Glisson. We may conclude this part of the subject by quoting David D. Davis, in his *Principle and Practice of Midwifery*, vol. ii, p. 1062: "In the treatment of this form of retention of the placenta, the proper, and indeed the only safe practice to be adopted, is to withdraw by careful detachment all of the placenta that is found not morbidly adherent to the uterine parietes, leaving the diseased remainder to such kindly offices of nature as she may be able to exert for their expulsion."

The above treatment is strongly sustained by the late Professor Hugh L. Hodge, of the University of Pennsylvania in his *Principles and Practice of Obstetrics*. He says: "Should the adhesions be very close, the accoucheur should content himself with lacerating the placenta, and bringing away as much of the mass as possible."

The rigor occurred on the eighth day after her delivery, and was due undoubtedly to pus, or its constituents, being poured into the blood. At this period according to Wenheimer, the microscopical constituents of the lochia are no longer serous, but consist of pus corpuscles, and they are the paramount constituent. It was at this period that pyæmia supervened, owing to the presence of pus, as a natural result of inflammatory action, rendered infective by the vital depression of the patient. Had her condition been otherwise, in accordance with the principle discovered by Lister, and which is now generally admitted, viz.: that the tissues of a healthy living body have a power of counteracting the energies of bacteria in their vicinity and preventing their development—a favorable prognosis might have been predicted.

From the birth of the child to the eighth day, a compress, firm and snug-fitting binder was kept constantly applied, and ergot was administered to insure uterine contraction, and to prevent absorption of purulent products; strict quiet and cleanliness were enjoined, and the nurse instructed to use vaginal injections of carbolized water twice or three times a day. Quinine was given with proper food.

On the 21st of March, (the eighth day after her delivery) a severe rigor occurred, followed by a sharp rise of temperature. The fever took an acuminate form, for after the temperature reached the highest peak, it began immediately to fall again. This sudden turning back of temperature after reaching the maximal point, and rapid downfall of temperature, recurred several times during the twenty-four hours and became the most marked feature in the case. Thomas thus alludes to the fluctuations in temperature.

"In the morning the temperature would be found at 102°, in the evening of the same day 106°; the following morning it would be 98°, and toward evening of the same day 106° and 107°. The thermometric evidence is the most valuable we have, in every respect it is the most serviceable, and certainly wonderful." He thus truly describes the condition of our patient when he says: "A patient may look perfectly well in the morning, and in the evening have a temperature of 107° or 108°, which is a fact of itself to indicate to us that she is suffering from some very great disease."

These fluctuations in temperature were accompanied by a frequent pulse, 140, and hurried respiration, 44, great muscular debility, but without delirium or mental disturbance. These phenomena recurred each day until the 28th when the disease terminated fatally.

GENERAL TREATMENT.

Large doses of quinine, ten or fifteen grs. every six hours, beef essence and stimulants in large quantities, iodoform internally, as recommended by Professor Maggioli of Rome, frequent ablutions and speedy removal of all sources of infection, complete ventilation and the free use of carbolic acid.

SPECIAL TREATMENT.

As all possible sources of the poison should be removed, and where these consist of decomposing retained substances within the uterus or vaginal canal, it would be natural to suppose that intra-uterine injections would suggest themselves, and brilliant results are reported as having followed this special line of treatment. Renewal of the infection is thereby often rendered impossible, and if the case be one complicated by retention of clots or portions of an adherent placenta, this treatment is said to be especially serviceable.

Schonlein directs that in all cases where a recently-delivered woman has an offensive discharge from the uterus or an increase of temperature, he at once directs intra-uterine injections consisting of carbolized water. He publishes a table of 1,200 cases, for the purpose of demonstrating the great benefits derived therefrom.

Richter administered intra-uterine injections to

3,000 lying-in women without a single accident. If there be premature cessation of the lochia, with constitutional disturbance, a purulent discharge, foetid, and with increase of temperature, or if the uterus contain fragments of placenta, clots, or is imperfectly contracted, intra-uterine injections should invariably be used.

Dr. W. Gilwylis says: "If after labor a chill be followed by a rapid rise of temperature, I would wash out the uterine cavity with a solution of carbolic acid, one to twenty."

Dr. Grailly Hewitt uses carbolic acid by intra-uterine injections in all cases of pyæmia, and insists upon the necessity of drainage of the vagina by alteration of position.

Prof. Tarnier, of Paris, as a germicide uses bi-chloride of mercury solution, 1 to 1,000. He uses intra-uterine injections in pathological conditions only.

You are all, no doubt, perfectly familiar with the discussion before the New York Academy of Medicine, and with positions notably taken by Professors Barker and Thomas. It is not deemed necessary to allude to them specifically, only that Thomas is a strong advocate for carbolic acid, to be used freely and frequently in intra-uterine injections, while Barker deems these precautions as unnecessary, and sometimes positively injurious.

In looking over the literature of this subject I have failed to find any reasons given for the frequent intra-uterine injections of carbolic acid. It is true, we are informed the acid is a germicide, that it will destroy the organisms; and it is to this part of the subject that I will invite your closest attention for a few moments.

Microbe is a word for various minute organisms found in the fluids or tissues of the body in pyæmia and other diseased conditions.

They consist of cells of different sizes and shapes, which multiply themselves with enormous rapidity. Let it be distinctly enunciated that the doctrine of spontaneous generation is dead, and that it is established beyond dispute that the most putrescible bodies exposed to contact with the atmospheric air will remain unputrefied if preserved from contact with microbes or germs. Also, it is proven that the most extraordinary differences exist between the tenacity of life exhibited by the developed microbes and the spores or forms from which they spring.

Submit the microbes to boiling heat and they are killed; dry them and they die at once; expose them to oxygen and they perish; carbolic acid will paralyze them; expose any of them to oxygen under high pressure and they die.

Antiseptic agents kill them.

But the spores which they produce and from which they spring, are almost indestructible. Dryness only enables them to resist destruction; time is no object, for their dormant vitality is maintained for years. They have survived the boiling process for eight hours. Their immediate destruction is by the flame of the spirit lamp only, and yet we believe and teach that germs are readily destroyed by mild solutions of carbolic acid, bi-chloride of mercury, chloride of zinc,

and permanganate of potass., and that by the effective application of the agents above mentioned, we can protect our patients against the mischief they work. If this be true, and no one will deny the statement who is well qualified to pronounce judgment, it seems to me to be a most important point to be carefully considered in treatment of cases in medicine, surgery and obstetrics.

Now, let us refer to the experiments of Prof. Tyndall, and see if they do not offer the solution to the phenomena referred to. He took infusions, infected with spores derived from old hay, on which many hours of continuous boiling had no effect, but found that by boiling for a single minute at intervals of a few hours, he could, with an aggregate of five minutes' boiling, sterilize the most refractory infusion. And now follows the explanation: The spores in an infusion are in different conditions as to species, age, humidity, dessication, exposure to light and heat.

They will require different periods for germination; while they remain simple spores, they resist boiling because they are endowed with the most robust vitality. But allow them to germinate, and deal with each successive crop as it is springing into life, and your victory is complete and of the easiest. It is in this manner that germicides accomplish all that is claimed for them. They kill the developed microbe, and prevent the development of others. They will kill them off in detail, as they spring into life or are developing into maturity.

You will now apprehend why I believe in the antiseptic intra-uterine injections in those pathological lesions tending to develop the pyæmic process; by the *repeated* application of carbolized solutions we destroy the microbes as they germinate, and hence it is now easy to comprehend the success claimed so recently by Prof. Thomas, by this method, and the reason why the almost unceasing intra-uterine injections are necessary to arrest the pyæmic process.

In the above I have presumed the connection of cause and effect as existing between microbes and the diseases with which they are found associated.

Of the methods by which it can be proved that they really stand to each other in this relation, I have only to refer to the proofs offered by Burdon-Sanderson, Koch, Pasteur, Toussaint.

APPENDIX.

After the above paper was concluded the following letter was addressed to H. V. Sweringen, M.D., and we here publish his reply:

H. V. SWERINGEN, M.D.:

My dear Doctor:—I would indeed thank you for a note containing a statement of the impressions entertained by you while Mrs. Ellison's case was under your observation; during the interim I was ill and unable to attend. Faithfully,

W. H. MYERS.

Fort Wayne, Ind., July, 1884.

FORT WAYNE, Ind., 1884.

W. H. MYERS, M.D. *My dear Doctor*:—Your note requesting a statement of the case of Mrs. Elli-

son, during the time she was under my care, has been received, and I now cheerfully comply therewith.

On the day following her delivery and upon which you were taken ill, I was requested to visit her merely for the purpose of relieving her bladder.

After the lapse of seven days, at about 1:30 o'clock on the following Thursday morning, the 20th, I was called the second time to see her, because of a violent chill with which she had been attacked soon after midnight. Her temperature at this visit was 106° F., but in a very short time, during a copious perspiration, declined to about 100 or 101.

Agreeable to the most approved treatment in these cases, regarding her case as a typical one of puerperal pyæmia, resort was now had to intra-uterine injections of carbolyzed warm water and to the internal administration of quinine, ten grain doses, at intervals of four hours. For a time she seemed greatly improved and apparently approaching convalescence. Suddenly, without any premonition, she was taken with another chill, which was accompanied with the same phenomena already referred to. And so chill after chill followed each other in irregular succession, each attended with a rapid rise and decline of the temperature with profuse sweating. The pulse after the third rigor had attained an acceleration of 140, and evidences of great exhaustion were now beginning to be manifest.

Upon making inquiry of the husband I learned of the difficulty you had in extracting the placenta. I concluded that you must have had one of those rare cases of true adherent placenta, in which it is utterly impossible to effect its entire separation, the union being so firm. I then remarked to Mr. Ellison that the cause of this adhesion must certainly have been due to the injury she sustained in the accident which befell her a few months prior, for reasons which you will readily understand, and I believe this accident rendered her general system illy prepared to resist the influence which the difficult extraction of the placenta would exert in consequence of the septic dangers it would occasion.

Very truly yours,
H. V. SWERINGEN.

ADDRESS IN OBSTETRICS AND DISEASES OF WOMEN.

BY THAD. A. REAMY, M.D., OF CINCINNATI, OHIO,
CHAIRMAN OF THE SECTION.

[Read in General Session of the American Medical Association, May, 1884.]

FELLOW MEMBERS:—Custom, as well as law, prescribes as one of the duties of the Chairman of a Section that he present in his annual address a digest of the progress made in that special department during the past year.

Compliance with the letter of this law is now unnecessary, and would, therefore, be unprofitable.

Medical journals, general and special, both home and foreign, conducted with great ability and exhibiting much energy and zeal in collecting and publishing the latest advances in all departments, are promptly placed by rapid mail facilities upon the table of every reading member of the profession. Moreover, the editorial criticisms of new doctrines, discoveries, methods or operations, are generally from the pens of those who, by education and special training, have superior abilities for such work. It is, therefore, deemed appropriate, on the present occasion, to refer you for an "Annual Report on Obstetrics and Diseases of Women" to these more fertile and instructive sources.

Craving your indulgence, I beg to offer, in lieu of such an address,

NOTES OF TWO HUNDRED AND THIRTY-ONE CASES OF OPERATION FOR LACERATION OF THE CERVIX UTERI.

The date of my first operation for lacerated cervix, "Emmet's operation," was February 28, 1874. I have now made the operation upon 231 patients. Not a single death has occurred. In six cases the operation was followed by perimetritis, parametritis or peritonitis. In but three of these cases, however, were these symptoms sufficiently severe to cause material delay in complete recovery. In one case, included in these three, there was perimetritis, parametritis, and general peritonitis. The patient was confined to her bed for three months. During the attack (acute stage) the peritoneal cavity was aspirated twice. On one occasion seventeen ounces of serum were removed. This woman finally recovered her health perfectly. Considerable fixedness of the uterus remained for a long time; but now, at the expiration of two and a half years, uterine mobility is about normal, menstruation normal and painless, whereas prior to the operation she suffered both from menorrhagia and dysmenorrhœa. She was the mother of two children, the youngest being 4 years old at the date of operation. No abortions had occurred. Sterility continues. The above case was one of bilateral laceration, extending on each side to the vaginal junction, the torn lips being widely separated and eroded. I attribute the inflammatory complications following the operation in this case to the undue degree to which the uterus was dragged down in order to give unobstructed access. On this point I shall have something further to say before the close of this paper.

Complete recovery occurred in the other two cases, but convalescence was slow.

Of these 231 cases, in 170 the laceration was bilateral, in 38 unilateral. Of these latter, 23 were on the left side and 15 on the right. Sixteen cases were stellate, in two of which there were four distinct lacerations. In five cases there was laceration of the posterior lip only, in two, of the anterior lip only. In 80 cases the laceration was extensive; in 15 of these 80 extending to the cervico-vaginal junction on both sides. In 22 of the bilateral cases the laceration extended to the cervico-vaginal junction on one side only. In three cases the rent extended to the internal os. In one of these, the vaginal wall was

likewise extensively lacerated; the peritoneal cavity had probably been opened, followed by protracted cellulitis. This patient remained a helpless invalid during the three years intervening between the accident and the date of my operation. On one side it required 12 sutures to close the cervical and vaginal rent. Perfect success followed the operation, the patient being restored to robust health within six months.

In 167 cases there was perineal laceration to an extent that left deformity, either at the vaginal orifice or more externally. In 15 cases the anal sphincter was damaged. In 7 cases the recto-vaginal septum was opened up. In 26 cases I operated upon the cervix and perinæum at the same sitting. In 5 cases of this series I curetted the uterus with my blunt wire curette at the same sitting, this of course, being the primary of the three procedures. In neither of these five cases did a single untoward symptom arise. Results were perfect.

In 50 cases I operated upon the perinæum after recovery from the cervical operation. Each of the cases above mentioned in which the operation involved the recto-vaginal septum is included in this series of fifty subsequent operations.

It is perhaps as well to state here that I never hesitate to curette the uterus in a case demanding it, at the time of operating upon the cervix. Nor do I hesitate to use the curette in a case requiring it immediately preceding a perineorrhaphy, pretty extensive clinical experience having convinced me that neither of these operations adds materially to the danger of curetting. Indeed, I am inclined to the opinion that in certain cases where the conjoined conditions demanding the two operations exist, the depletion of the cervix in trachelorrhaphy presents an element of safety against inflammatory processes which may follow curetting. Three violent cases of traumatic peritonitis have occurred within my personal experience from the use of the curette, unconnected with other operations. In not a single case of trachelorrhaphy performed by me did secondary hæmorrhage occur.

In every case where hæmorrhage was troublesome during the operation, it was readily controlled by the stream of hot water which it is my custom to have flow upon the field of the operation during its progress, with but three exceptions; in which it being necessary to denude the torn surfaces deeply, twigs of the circular branch of the uterine artery being cut, compression with torsion forceps was invoked. Contrary to most operators I have not, since my fourth operation, employed a tourniquet, ligature, or any similar method to control hæmorrhage during the operation. As early as 1875, in my clinical lectures delivered in the amphitheater of the Good Samaritan Hospital, and repeated each year since, I emphasized the importance of allowing, in most cases, free bleeding from the denuded surfaces. Firstly (*a*) because it softens the tissues so as to allow more perfect coaptation of the lips to be united; and (*b*) because of this softening, which is immediate, the tissues are easily penetrated by the needles in carrying the sutures. Secondly, and more important, this depletion not only greatly promotes the return of the indurated cervical

tissue to its normal condition, but is an immense factor in again starting the processes of involution of the uterus which had been arrested by the laceration and its consequences. The restoration of form in closing the divided lips of a torn cervix, especially where the deformity is great, is important. The removal of such pathological conditions as may threaten the development of cancer, and no one can deny that this is in a certain proportion of instances within the scope of the operation, may be even more important; but the influence of trachelorrhaphy, properly done, upon subinvolution cannot be over-estimated. Thorough denudation, cutting out all cicatricial tissue, and allowing free depletion, embrace the essential points in the operation so far as its influence upon involution is concerned.

So powerful is the influence of hot water in controlling hæmorrhage from small vessels, when it can be poured directly upon the bleeding surface, that I have frequently found it expedient to withhold this agent for a short time after the denudation is completed before introducing the sutures, in order that sufficient bleeding may occur to accomplish the ends above indicated.

The character of the labor which had resulted in laceration could not be determined with any degree of certainty, except in comparatively few instances, since information upon this point could be obtained only from the patients themselves. In 40 cases delivery was accomplished by the forceps; in 2 by craniotomy; in 2 by turning. Two of the cases where rupture involved the recto-vaginal septum, were forceps deliveries.

It is my belief that early rupture of the membranes, and attempts at forcible dilatation of the cervix by the finger or fingers of the accoucheur or midwife, and the improper use of ergot, are far more fruitful sources of laceration to the cervix than the obstetric forceps.

In the city of Cincinnati 70 per centum of all deliveries are attended by midwives, who, with very few exceptions, are ignorant and unskilful. The sins above enumerated lie closely at their doors. But it cannot be denied that these errors of practice are sometimes perpetrated by well educated physicians. Unquestionably, many cases of laceration occur unavoidably, no matter what care and skill may characterize the accoucheur's services. It should be the duty, therefore, of the gynæcologist in all cases where patients are referred or otherwise come into his hands for operation, to protect the physician who may have been present at the confinement against censure, which may be unjust. All the more because the laity, when informed that a laceration of either cervix or perinæum has occurred, at once assume a want of skill or care in the obstetric service. The emphatic statement of the unavoidableness of these accidents should by the gynæcologist be voluntary. So great is the danger that professional reputation may unjustly suffer from this source of censure, that in an editorial in a recent issue of one of the ablest medical journals of the country, this was used as an argument against the adoption of Emmet's operation except in extreme cases.

Mr. Jonathan Hutchinson points out that in many cases the first stage of cancer is that of inflammation; that "all inflammations are infective." "Inflammatory processes may pass by almost imperceptible gradation into malignancy." The acceptance and appreciation of the above facts would lead in many cases to the more vigorous treatment of localized inflammations; more especially when situated in structures known from clinical experience to be specially prone to cancer, as the uterine cervix, mammae, etc. These considerations alone, even if they were not supported by others, urge with great force upon our attention the importance of Emmet's operation. It is the concurrent testimony of almost every distinguished American gynaecologist who has spoken on the subject, with many abroad, including Briesky and Schroeder, that the fretting of exposed tissue consequent upon ununited laceration of the cervix is a prolific source of danger in developing cancer.

Emmet, Thomas, Goodell, Mundé and others have cited cases verifying this danger. In my own practice quite a number of cases of cancer of the cervix have been observed where the neoplasm developed either in the cicatricial tissue resulting from laceration or in the apex of the cleft.

In my opinion, the influence of the accident under discussion in producing cancer has never been fully apprehended by any one. Emmet, the distinguished author of the operation under consideration, at first spoke out unequivocally. Now, however, he alleges that he does not make trachelorrhaphy once where formerly he did it ten times; and it is easy to read between the lines of what he has recently written, that he does not now believe the evils arising from laceration not operated on, nearly so universal as he formerly believed them to be. He seems greatly to deplore the extent to which the operation is being done, and as I think, without just cause.

In further considering the relations between this injury and Emmet's operation to cancer, it may not be amiss to call attention to the fact so thoroughly recognized by clinicians, that cancer of the cervix is found almost exclusively in women who have either given birth to one or more children or been the subjects of abortion. So far as the cervix is concerned, cancer is a disease of childbearing women, not of virgins. In more than 300 cases of cancer of the cervix of which I have notes but one occurred in a virgin, and but ten in married women in whose cases I could obtain no evidence of abortion or childbearing. Can any one deny that such facts point strongly to the local origin of cancer in these cases at least? And can it be doubted that injuries inflicted upon the cervix during parturition have a direct or remote connection with this origin? Would it not be wise to repair these injuries when they are appreciable by whatever method it may be done most speedily and certainly? It is claimed that Emmet's operation should be limited to cases where ectropion has occurred, or where a cicatricial plug imprisons or presses upon branches of sentient nerves, causing painful reflex symptoms. I have heard it repeatedly stated that no matter how extensive the laceration, the operation is not warranted unless these symptoms

are present. These are in my judgment errors. Any laceration which has healed without its surfaces being in contact must have healed without complete union, although its extent may have been much lessened by granulation. But in all such cases there is more or less cicatricial tissue in the field of repair. (This does not apply to the many cases where anterior and posterior laceration occurs, and the parts not being separated complete union has occurred without the aid of the surgeon). Cicatricial tissue in such locality, even should it not produce reflex symptoms, should be removed thoroughly and the parts closed so as to obtain union by first intention, in which cicatricial tissue is never found. If the rent be small, then the operation is small, especially if it be done before chronic inflammation of the cervix has occurred, as a result. The denudation need not be extensive or deep. In many cases an anæsthetic need not be administered, as the parts are not very sensitive. The uterus need not be drawn down, so there can be but little danger of cellulitis or peritonitis resulting. Why not do the operation in these slighter cases, then, as the simplest and safest method of cure? thus avoiding results which might arise in the future and prove more serious?

It is impossible for me to give exact data as to the influence of the operation on sterility, as many of these cases soon after recovery, passed out of my knowledge. And as the last 50 cases were operated on within the past thirteen months, sufficient time has not elapsed to test the question. I know, however, of 15 cases where conception has occurred, and delivery took place at term. I have no doubt that as many more have proven fruitful. Of these I attended in labor 6, one of these within the past month. In no case did relaceration occur, labor being normal except in two cases. In these dilatation of the cervix was slow, but finally complete, in neither case was it protracted. I have learned from medical gentlemen who attended several other of my cases that labor was normal. I believe that the operation properly done, favors fertility, and often cures sterility.

In but 2 of my cases did union fail. In one of these I foolishly used catgut ligature. In the other failure was due to the sutures not being sufficiently tightened. In each case subsequent operation was successful.

I may have made the operation in cases not demanding it, but from my point of view, I do not think so. In 8 or 10 cases reflex nervous symptoms, which I hoped to banish by the operation, remained, but in most cases the good effects were obvious; in some cases the cures were almost marvellous.

My method of operating, after much thought, and some experience I think worthy of consideration, as it must, as I believe, have some advantages over methods generally adopted.

1. I use nothing to draw the uterus down with but the single vulsella, with which I seize but one lip, the one to be denuded first, at a time.

2. I draw the uterus down as little as possible. This caution should be the more scrupulously observed, if any cellulitis remains about the base of the broad ligaments or elsewhere.

3. I outline the denudation with a sharp knife, and then cut the tissue included in the line with a sharp scissors. This prevents the rolling of tissue at the borders.

4. Allow bleeding freely or not, as the condition of the tissue of the cervix and the involution or subinvolution of the uterus may require.

5. Use a nearly half-circle needle with very sharp point, armed with Chinese silk.

This shaped needle can be drawn through the second lip and withdrawn very much more easily than a straight needle, or one curved only near the point. This advantage is all the more apparent when the uterus is not drawn down, as then the vaginal wall makes the withdrawal of the usual shaped needle difficult. I employ a plain needle-holder without any catch or slide, but strong.

Silk is preferred to wire because it can be tied much more quickly, and the tension more easily adjusted. Then there are no ends to jag the vaginal walls.

Another great advantage of the silk over the wire is in the fact that the sutures may be left in 15 to 30 days, without danger of cutting out—quite an important matter in a case when trachelorrhaphy and perineorrhaphy are done at the same sitting. The perinæum may perfectly heal and be strong before removing cervical sutures. My custom is to allow the ends of the sutures to remain sufficiently long to reach nearly to the vaginal opening. This facilitates their removal.

6. Wash out the cervical canal at the close of the operation with a recurrent flow syringe to remove any blood that may have found its way there during closure of the sutures.

Have nurse wash out the vagina with warm carbolized water, within an hour after the operation is completed. The vagina is not syringed again until the sixth day, then daily until the patient is dismissed.

Cleanliness is the only antiseptis employed.

Authorities have been but little quoted or referred to, as it was my purpose in this paper simply to give notes of my own cases.

NOTE.—According to my observations, about one out of every nine women suffers laceration in first confinement.

ESSAY ON DESPERATE SURGERY IN ITS RELATIONS TO WOMEN; THE PROPER PLACE FOR IT; WHO SHOULD, AND WHO SHOULD NOT ATTEMPT IT.

BY R. S. SUTTON, M.D., PITTSBURGH, PA.

[Read in the Section on Obstetrics and Gynecology of the American Medical Association, May, 1884.]

MR. PRESIDENT AND GENTLEMEN:

By desperate surgery I mean operations that endanger the life of the patient.

As they relate to women, such operations are largely intra-abdominal.

That the opening of the cavity of the peritonæum is desperately dangerous, will be denied alone by persons ignorant of American statistics tabulating the results of this kind of surgical interference.

That this subject is worthy of intelligent and intense investigation, is claimed by all who honor the profession of medicine, desire to ameliorate the condition of suffering humanity, and wish to prolong life.

The presentation of a tabulated statement of the intra-abdominal surgical operations performed more or less frequently, will serve to bring the subject clearly before our minds. These are:

- 1, Normal ovariectomy, Battey's operation.
- 2, Removal of the ovaries and tubes, Hegar-Tait operation.
- 3, Ovariectomy for cystic ovaries, McDowel's operation.
- 4, Enucleation per vaginam of the entire uterus, Langenbeck's operation.
- 5, Supra-vaginal hysterectomy, Clay's operation.
- 6, Enterotomy, Ramdohr's operation.
- 7, Gastrotomy, Sedillot's operation.
- 8, Resection of the pylorus, Billroth's operation.
- 9, Removal of the gall bladder, Langenbeck's operation.
- 10, Cholecystotomy, Marion Sim's operation.
- 11, Hepatotomy for hydatids, Lawson Tait's operation.
- 12, Nephrectomy, Simon's operation.
- 13, Nephrotomy.
- 14, Radical operations for hernia.
- 15, Laparotomy for pelvic abscess, Lawson Tait's operation.
- 16, Laparotomy for splenic abscess.
- 17, Laparotomy for hepatic abscess.
- 18, Laparotomy for chronic peritonitis, Lawson Tait's operation.
- 19, Laparotomy for acute peritonitis, Lawson Tait's operation.
- 20, Laparotomy for hydatids of peritonæum.
- 21, Laparotomy for extra uterine foetation, Tait's method.
- 22, Supra-vaginal hysterectomy in pregnancy, Porro's operation.

In this enumeration there are twenty-two operations within the peritoneal sac, and it is probable that this number will be increased in the near future.

These, with laparotomy for diagnostic purposes, are included in my definition of desperate surgery in relation to women.

May I proceed a step further and characterize this class of surgical operations as a special field of work?

May I affirm that abdominal surgery constitutes a great and growing specialty?

May I predict the gradual limitation of that now ascendant specialty, gynecology, caused by the special surgeon usurping its abdominal prerogatives?

Is not this the form we see outlined in the shadow of coming events?

It is an admitted fact that when certain organs within the cavity of the peritonæum become diseased, the surgeon's knife is the only available medicament.

Truly the successful gynecologist is the one that handles the implements of the surgeon skilfully, and

he who does not possess this aptitude, is, in this department, a failure.

For illustration :

The cervix is no longer ulcerated ; it is lacerated, and a surgeon only can treat it successfully.

Yes, gentlemen, I am bold to predict that, within a few years, the specialty of abdominal surgery will be established, and limit the place and prerogatives of that other specialty, out of which it is rapidly growing.

This new specialty is already challenging the attention of intelligence ; and if it secure the might of mind, courage of heart, and dexterity of hand its work requires, it will command universal admiration.

In our country, this branch of surgery is in a most unsatisfactory condition.

From this sweeping assertion, I except the city of Boston, Mass., in so far as ovariectomy is concerned.

And because of the many favorable opportunities with foreign operators of great success, that have been enjoyed by me, I feel that a special obligation to seek its advancement by public discussion, rests upon me.

This is my purpose in this paper.

The second topic proposed is the inquiry : What constitutes a proper place for this kind of surgical operations ?

Is it the general hospital with its pus-soaked wards and atmosphere laden with all sorts of deadly germs ?

Is it the modern city residence with its malodorous environment, defective sewerage, and coterie of curious relatives and acquaintances, that refuse to be kept at a distance by quarantine regulations ?

Is it the cottage by the roadside, with its freedom from noxious gases, and bathed with clover scented air, delightful and health-giving ?

Shall we select the hermitage on the secluded mountain slope, with its widely varying temperature, or the lodge in some vast wilderness of forest, with its continuity of shade and moist coolness ?

Viewed from these points, these rural retreats may each be denominated an elysium ; but the indispensable nurse is not found there, and the doctor is a league away.

With the nurse present and the physician within prompt call, any one of these places would satisfy the most scrupulous surgeon ; but the absence of these elements of success, renders them forbidding.

And even with these disadvantages, men of experience give them a decided preference over the general hospital.

We will be materially aided in replying to this inquiry, if we enumerate the elements of safety required in every house, in which abdominal section is contemplated.

These are :

- a. A large airy apartment properly prepared.
- b. Freedom from the presence of all zymotic germs.
- c. An edifice exposed to the sun, and surrounded with a capacious air space.
- d. Perfect sewerage.
- e. If in a city, a house located in a quiet neighborhood.

f. A population that will respect the quarantine of the patient for at least a week after the operation.

These desirable conditions should be under the control of a conscientious nurse, and the surgeon should be near his patient, so that everything may be under his constant supervision.

Gentlemen, I firmly believe, that these provisions of safety are best secured in a private hospital, and that when all engaged in this line of work so decide and act, our statistics, now so deplorably bad, will greatly improve, and possibly may attain those of Dr. Keith and Mr. Tait, who perform their operations largely in private hospitals.

The ground for my belief that the private hospital is, as a rule, the best place for abdominal surgical operations, is the fact that the statistics of this class of surgery show, that by far the best results have been obtained in private and special hospitals.

Our third topic relates to the persons performing these operations.

Who ought, and who ought not to undertake them ?

The general practitioner, who daily passes from scarlet fever to diphtheritic or erysipelatos cases, has no warrant for opening the abdominal cavity.

On the other hand, the accumulated testimony relating to infection from these sources, render it probable that he who does this, will destroy life and make himself liable to criminal prosecution.

The general surgeon, at a time when he is attending foul wounds, or engaged in any pathological work, is, in the light of knowledge gathered from experience, criminally careless, if he open the abdomen.

The obstetrician attending cases of puerperal peritonitis, or other zymotic disease, has no right to imperil a woman's life by exposing her vital organs to noxious infection.

The gynæcologist in attendance upon a patient with a fetid cancer of the uterus, would probably be a minister of death to a woman, whose abdomen he would presume to open.

Men laboring among infectious diseases should know that their clothing becomes a magazine filled with deadly missiles, and their surgical case a quiver stocked with poisonous arrows, and if they attempt these operations, the result will be almost certain failure.

The history of the past and the best judgment of the present, unite in declaring that a specialist for abdominal surgery is the man who should attempt this dangerous work.

He ought to be excluded from general practice and other surgery, avoid all causes of infection, and when accidentally exposed, should sacrifice his clothing, and employ the best germicides thoroughly and repeatedly before resuming his work.

He should shun all sorts of zymotic diseases as scrupulously as did the Jewish High Priest bodies of the dead.

I am aware, gentlemen, that this doctrine has the appearance of puritanism, but it should be borne in mind that the successful abdominal surgeon is a literal purist.

It may be objected that it debars the young practitioner from exercising his gifts, as it is not practicable for him to abstain from general practice for the

sake of the few abdominal sections that he may have opportunity to make.

But let me address a word of advice to these worthy men.

If you cannot afford to abjure the rewards of other kinds of professional service, to stand by the operating tables of specialists until you have acquired the knowledge and skill to make you a specialist, the interests of suffering human beings, of the honor of the profession, and of your own financial condition, require you to send cases needing such surgery to the men who have made the sacrifice and endured the toil of acquisition that fits them for this kind of work.

Emergencies may occur when a specialist is not within reach. Then it is wise to select the best man, put him in the best condition possible as to cleanliness and assistance, and commit the case to his care.

Above all others, this specialty is intolerant of mistakes and mismanagement.

The laws of nature forbid that men who treat zymotic diseases in city practice, and dress sloughing wounds so frequent in railroad and factory cases, should obtain good results, and write a high rate of recoveries in abdominal surgery.

Your speaker is unable to name a single man who has made a fair reputation, who has not made it in a specialty.

If there be a general surgeon in this country who can show a record of 83 recoveries in 100 cases of ovariectomy, let him speak out and challenge the truth of this assertion.

Both Dr. Keith and Mr. Tait have shown 98 per cent. of recoveries.

It is admitted that Dr. Keith has done some general practice; not much, however; and his opinion is in favor of the secluded surgeon.

Mr. Tait is a thorough specialist.

My own experience, in a private hospital, is limited; but I am able to say, that all my operations performed in my private hospital since it was opened, last September, have recovered, and some of these are graver than those I constantly lost previous to obtaining this essential condition of success.

There, during the past winter with its unfavorable weather, I have made seven abdominal sections, viz.: one supra-vaginal hysterectomy for deformed uterus; one supra-vaginal hysterectomy for fibroid tumors; one double ovariectomy for cystic tumors, and a supra-vaginal hysterectomy on the same patient, and four ovariectomies. All these have made good recoveries.

Previous to opening my hospital, my results were bad; now they are very encouraging.

Mr. Tait in his early operations, without a private hospital, was very unsuccessful, and his present excellent results are due to seclusive hospital privileges, and abstaining from general practice.

Mr. Tait's colleague, Dr. Savage, of Birmingham, who, in his last published 85 cases of abdominal section, lost but four patients, said to me, when speaking of Mr. Tait's success, "He is not mixed up with diseases in general practice."

Said Dr. Keith to me, referring to abdominal surgery, "When you begin to do these operations, all other practice will leave you."

Speaking of those who succeeded and those who failed in ovariectomy, he said to me, "Before I began to operate, ovariectomy ruined a number of surgeons in Edinburgh."

Why did it not ruin Keith?

It was because he bought a flat of desirable rooms on the top of a well located building, and there fixed his private hospital, despite threats of prosecution.

Sir Spencer Wells owes his success to the seclusion of the Samaritan hospital, and Martin of Berlin, in his private hospital, has had a line of more than fifty operations without a death.

And Mr. Thornton reports seventy (70) operations without a single fatal result at the Samaritan hospital.

I challenge the production of a single operator outside of a private or special hospital, who can show better than eighty-two recoveries in one hundred cases.

On the other hand, I ask you to observe that every man who can produce better results, and is able to exhibit a better record, has either a private hospital, or similar exclusive facilities.

I conclude this paper with the assertion that to be successful abdominal surgeons, we must keep ourselves free from the infection of zymotic diseases and foul wounds, and give scrupulous attention to every detail of cleanliness in ourselves, assistants, nurses, sponges, instruments, patient and her environs.

If men are not prepared to do all this, they have no warrant for opening the abdomen of any woman, except in a case of emergency, where they alone can make an effort to save imperiled life.

DISCUSSION.

Dr. McLean, of Michigan.

Mr. Chairman:—This subject of ovariectomy is one to which I have given a great deal of attention. I have not only performed it a considerable number of times myself, but I have seen distinguished operators perform it. I have watched the whole subject from its very inception. I was a student in Edinburgh at the time that Keith performed his first operation before that Faculty. I have watched with very great interest and with very great care the progress of professional opinion with regard to ovariectomy, and I have watched the career of the great ovariectomists very closely indeed.

While, no doubt, there is theoretically a great deal of truth in the doctrines laid down in the paper which we have just listened to, there is (and I am sure very many of you will agree with me) a great deal that is utterly impracticable and discouraging. It may be all very well in a small country like Great Britain, where a few hours of railway travel will carry the passenger to Edinburgh, to London, to Manchester, or to Liverpool, and where there is, besides that, a great deal of concentrated wealth,—it may be all very well to lay down the doctrine as to who shall perform ovariectomy, and where it shall be done. But in this vast and comparatively poor country—a country of "magnificent distances"—it is impossible to place all our patients under these favorable circumstances. We have to do the best we can with them. I ask you, Where did ovariectomy spring from? Not

from London. It did really spring from Edinburgh, not practically but theoretically, from Dr. Bell, of that city. But where was it performed? In the back-woods of Kentucky. And at this very day there are many cases where patients have but one of two things to do—to go down to death, or to submit to the operator who has the courage and the heart to operate upon them. Now, I say, for any person who happens to live in the city, and happens to have the means to establish a private hospital, who happens to be in a railroad centre, to come forward here and lay down the doctrine to this great nation of surgeons and practitioners, “You shall not perform ovariectomy; let your patients die or send them to me!” such a proposition is, to say the least, presumptuous! (Applause.)

I do not live in a great railway centre. I live in Detroit. I am a general practitioner, a general surgeon and railroad surgeon. Since the first of October last, I have performed five cases of ovariectomy—one at the University of Ann Arbor, in the presence of the class; one in a “cottage by the roadside,” and three other cases. And my five patients have recovered. (Applause.) Now, am I, in view of these theoretical doctrines, to abandon my privilege of performing ovariectomy? It would take a great deal more eloquence and much more high-sounding sermons to convince me of that doctrine!

What was Dr. Keith’s statement to me? That he went directly from two cases of diphtheria to perform ovariectomy! He complained to me of private practice having left him. He said, “Ovariectomy is a very poor-paying business.” He told me what he had made since the 1st of January, and it was very small in proportion. Dr. Keith is a general candidate for practice of all kinds, and when I was in his office he examined a case of suppurating ear. This was in the month of August, 1880.

Now, I do not wish to enter upon any discussion here, to make any hard feeling of any kind whatever. But I do want to protest, with all the force of which I am capable, against any such centralization, any such discouraging, and any such monopolizing doctrine as the one we have listened to! (Applause.) For my part, it shall have no weight with me. I shall go on with my general practice, my general surgery, and my railroad surgery, with my best antiseptic precautions, and I shall encourage my students to perform ovariectomy when they are able to do it. I say, no man has a right to say I shall not perform ovariectomy, any more than that I shall not sing a song or make a speech! It is a matter for a man’s own conscience to decide for him. (Applause.)

Dr. Englemann, of Missouri.

Mr. Chairman:—One of the difficulties we meet with in the practice of medicine and surgery, is to blend the theory and the practice. I am certain that what Dr. Sutton has told us is theoretically most true. I have seen it for years in my own city. I mention it, because I believe the gentleman of whom I now speak, (and you will appreciate the force of the statement), Dr. Hodgkin—now dead—was acknowledged, outside of St. Louis also, as an able surgeon. Almost every case of ovariectomy in his practice died. He

was a successful surgeon and, I think, a skilful surgeon. His cases of ovariectomy died, one after another. I think he had but two or three successful cases. I have always attributed it to the fact that he practiced surgery and medicine, and had a very large practice and a practice involving many difficult cases. He was consulted far and wide, and had serious cases of old wounds and difficult amputations, besides other cases that would bring infection. His cases of ovariectomy were failures.

I believe that the law which Dr. Sutton wishes to lay down is, that absolute cleanliness is necessary. It is not carbolic acid or listerine. It is CLEANLINESS, that can be had in a village as well as in the city. But it is less difficult if we have the facilities of a hospital, such as he mentions. We are better situated. We have the opportunities. The surgeon himself keeps free from contamination, from diphtheria and typhoid fevers, all possible cases which might injure his surgical success. He has nurses—I will not say “trained” nurses, but “clean” nurses—and he is better able to do that. These surgeons who are engaged in the general practice of medicine, have not got those opportunities. Such a surgeon can do the same thing, but he does it with difficulty; and I have seen an entire hospital laid open to serious injury, to a perfect influx of sepsis, I believe, from the uncleanness of one gentleman who was present at an operation. Where every care had been exercised, one gentleman who had been present at post-mortems and the visits in general hospitals came, and it is presumed that is the reason so many cases of sepsis appeared at once. It is the hospital of Dr. Martin, to which Dr. Sutton has referred, where I saw, in wards and rooms, cases of the removal of the uterus and the extirpation of fibroids, patients lying side by side with laceration of the perinæum and extirpation of the uterus for cancer, and other cases of serious operations—and hardly an elevation of temperature in one of them—some six in a room and three in a room, and not an elevation of temperature anywhere. A case of lacerated perinæum began to show symptoms of sepsis, and the surgeon had to suspend the operation. Whether it was in the atmosphere or not, it was a most remarkable case. These serious operations—two or three cases of the extirpation of the uterus for cancer and fibroids—were without an elevation of the temperature; simply these little operations showed fever and high fever! There were three or four cases, two of them for laceration of the perinæum, which at once rose rapidly up in temperature, and no more operations were done for a few weeks.

The surgeon in one of these small places, and the general surgeon, is almost obliged to take men out of active practice for his assistants—to take men who are constantly treating cases of all kinds—and he injures his patients. It is ABSOLUTE CLEANLINESS which we wish to reach; and if any one is so fortunately placed as to be able to give up room and assistants for that, in one way I think he is doing good work. At the same time these operations are such as every surgeon and almost every physician is called upon to perform. He is obliged to do it often, and

then it is wrong for him to believe that only under certain circumstances can it be done.

A case of the kind is one whom a gentleman in New Mexico wished to send me—a case where inflammation set in, and the patient would have died, and of course, he had to do it there. I believe we should lay down the law of Absolute Cleanliness, and then let every one exercise it to the best of his ability. But I believe, if any one limits himself to it, and has the means for it, he is doing work in the right direction, and it may lead us to attempt doing—as closely as possible, at least—the same thing. The only law, I believe, for abdominal surgery, is **ABSOLUTE CLEANLINESS!** But, certainly, the skill and constant attention to a patient will facilitate materially, and that is only to be had by him who will devote himself more exclusively to it. If we could attain these conditions—if it were possible to attain these conditions which are striven for—it would give us better success; but, even in hospitals, I believe there is much to improve, and that, at present, these conditions are only in a few instances attained. It is only in a new hospital that Dr. Martin is building that I believe he will have such facilities. The location that he now has is in the second story of a tenement house; and I have always considered that the doctor's success was not due to his location, but due to his skill—was due to his **CLEANLINESS.** His present location is in the second story of a tenement house in a large city. The window of the operating room opens on a small yard where the filth of the house is deposited, where there are closets, and which receive the odors from the kitchen and other parts of the building. It is by no means what we should expect as a hospital; and his success, I may say then, is not due to location at all, but to the cleanliness of himself and assistants. The hospital that he is now building has an operating room for abdominal surgery, which has better advantages, and which can be flooded and washed with carbolic acid and other antiseptics. But at present, his work has been done under circumstances as little favorable as regards location as any one could possibly be situated. A tenement house is not a cleanly place; and I do not think that in his case we should lay stress upon that, but upon the cleanliness of himself and assistants—the nurses and everyone. But I should wish to see these conditions carried out here, if possible; and it will enable us to achieve similar success to that which is achieved abroad, though we must admit that in our abdominal surgery we do not obtain results which are achieved abroad. Originating in this country, we are now left behind. (Applause.)

Dr. Beach, of Ohio.

Mr. Chairman:—I simply rise to say, that I think the Section would be glad to hear from Dr. Alexander Dunlap, of Ohio, who has performed cases of ovariectomy more times, I believe, with one single exception, than any other surgeon in the United States. (Applause.)

Dr. Dunlap, of Ohio.

Mr. Chairman:—I will give my experience in the treatment of diseases, when called upon. I have

been engaged on this subject for over forty years; and, theoretically, the paper that was read to you is true, but one in which, as I look at it, the main part of the successes of these operations is entirely left out, and is always left out when you take the patients away from their homes to the hospital,—and that is, the condition of the mind. You take a patient who is thoroughly convinced herself that if the tumor is removed, the operation is performed, and she survives the operation, she is able and is going to get well,—you can place her almost in any position and she will get well. You may nurse her in almost any manner, and she will get well.

I had one patient who had been to three physicians and surgeons. They had all the time to operate, but they said it would be certain death to her. But she said she was going to be operated upon. She heard of me and came to Columbus. I would not put her in the general hospital there—the doctor had no place to put her, because there were cases of infectious inflammation in the hospital. I told her to go to some other place, and she afterwards informed me that she had got a room. It was in one of the lowest hovels in Columbus—negroes. I went there and operated on her, but that night the whole of them had got drunk and wanted to have a dance there. Two young men were the only ones there were left with her. I had to go home and came away. I did not know how bad the place was until I came back the next day—but it did not disturb the patient at all. She made a rapid and easy recovery. Now, the conditions around that patient were about the worst—but she showed confidence in me, and I would not operate upon a patient who supposed she was going to die. Place her in the best conditions or surround her with the best nurses, she must come to the conclusion that she is able to bear the operation and can get well; and if you can inspire the patient with that kind of confidence, she is going to get well!—nine cases out of ten! (Applause.) Yes, more than that will get well! All that the patient needs is quiet; and the operator who has the most time to give to it and gives to the patient every advantage, but takes her away from her home, away from her friends and to a hospital, will have that mental condition to contend against.

I do not believe so much in this doctrine that has been stated by Dr. Sutton. I do not believe in it at all. (Applause.) I am very careful to have my hands clean. I am careful when I go into a sick-room; but I am not afraid to go into any sick-room, for I know that within one or two hundred yards the atmosphere of it will be gone. In most contagious cases of small-pox—if you do not get that pus daubed on your clothes or on your hands—the atmosphere will be gone from your clothes before you shall have gone 200 yards from that house.

But there are times when misfortunes will follow the operators—follow them severely and closely, too. Now, in 1883, 1881 and 1882, almost every patient that I had in general surgery, as well as ovarian surgery—my ovariectomies died right off as fast as I could operate upon them. It made me so sick, that I could scarcely bear to hear of a case of ovariectomy.

I could stand one death, but when it came to about three in six weeks I became sick of it. (Laughter.) Now, within the last fourteen months I have performed twenty-three cases of ovariectomy, and lost only two; and of those two, one was 70 and the other 64 years of age, and so broken down in their conditions that I could scarcely have expected them to get well. (Applause.)

Now, I am not afraid to go to scarlet fever and then go to a case of ovariectomy, if I have only one day's time in which to air my clothes. But I am very particular about my hands and instruments, and not only that, but about cleansing the wound—to dry it up to the very bottom of it, to see that there is nothing left in that cavity of the abdomen. And I prefer that the patient shall be left in such a position that the drainage from the lumbar region shall go down to the pelvic region, so that I can know that I have got it all out. If you have the patient in a half-reclining position, the whole of it is drained right down into the pelvic cavity, into the sac, where you can get at it. It is very difficult, when you have the patient lying on the back and the loin is sprung up and the pelvic cavity is on one side and the drainage away up in the lumbar region, to get the intestines away so that you are sure that you have got it all out; and when I speak of "cleanliness," it is to see that there is none of the fluid left there. I have always opposed the use of carbolic acid in the abdominal cavity. Any one in the habit of putting the hand into a weak solution and holding it there awhile, will experience the sensation of numbness—you have paralyzed those nerves; and if you turn in and wash out the abdominal cavity with carbolic acid, you paralyze those nerves and cause the absorption of the fluid as it is borne out of the cavity. And at the same time you will notice that the kidneys, after using the carbolic acid frequently, are very slow in their movements. (Dr. Dunlap was here notified by the chairman that his time had expired.)

Dr. Bartlett, of Wisconsin:

Mr. Chairman:—Before Dr. Dunlap takes his seat, I would like to ask him a question. Can you give any reason, doctor, for the death of those three successive cases of ovariectomy? What was your explanation of it?

Dr. Dunlap: There were atmospheric influences passing over a large section of country—I do not know what they were. The weather was warm.

Dr. Bartlett (interposing): Did that same fatality occur in the same locality?

Dr. Dunlap: Yes, sir; I was practicing over the whole State of Ohio, and nearly all my operations were unfavorable.

The chairman, at this point (3:45 P. M.), announced that he had received information of the death of Dr. S. D. Gross, of Pennsylvania. It was moved by Dr. Bartlett that, out of respect to the deceased, the Section adjourn, to meet again at 4 o'clock P. M. Said motion, being seconded, was unanimously adopted, and the Section thereupon adjourned.

The Section was re-convened at 4 o'clock P. M., pursuant to adjournment, Dr. Gordon, of Maine,

presiding during the temporary absence of the chairman, whereupon the discussion upon the paper read by Dr. Sutton was resumed.

Dr. Quimby, of Jersey City, New Jersey.

Mr. Chairman:—I would like to say a few words in regard to the extremes of treatment and precaution. We have, on the one side, those who contend that a person should be almost set apart for certain operations—be kept in an atmosphere free from the fears of germs. We have, also, on the other side, those, with large experience, who say that they are not so very much alarmed,—they do not believe they are walking-magazines filled with bacteria and other things, and carry destruction all around them. I belong to that class, sir, who rather try to get the medium, and believe there are certain dangers to be avoided, and that cleanliness, of course, is the great thing to be observed. But I do not coincide with those who believe that any person should be set apart, as it were, on account of the danger of communication—provided that person is sufficiently cleanly.

I merely wish to make this remark: In our city, at one time, we had quite an epidemic of small-pox, which I think is considered pretty contagious. At that time, I attended a good many cases of small-pox, and attended, also, a good many obstetrical cases at the same time. It is a well-settled opinion that a person should not go from a small-pox case to an obstetrical case. I believe that to be true. Nevertheless, I attended all my small-pox cases and all my obstetrical cases (and I had some twenty of each on the list at one time), in their regular order, and all the precaution I took was to visit all my small-pox cases first, and then, after changing my clothes, I went and made my other visits, and even attended ladies in confinement, with no bad results. Of course, I was particular about cleansing my hands, changing my clothes, and even washing out my hair.

Now, I think that in any of these abdominal operations, all that is necessary is to observe strict cleanliness, and then we may adopt the Lister method or any other method as we may elect. Now, if there was so much danger of carrying these germs with us, it seems to me that in cases of small-pox they would have been carried. And while I think you should be cautious about cleanliness, I do not think there should be that fear, referred to in the paper that has been read here, by any person not exclusively engaged in such practice. I do not believe that anything is necessary except this cleanliness.

A Member: How often have you opened the abdomen?

Dr. Quimby: Well, I cannot say. For abdominal trouble, not more than six or seven times, and only about one half of them recovered. (Laughter.)

Dr. Robertson, of South Carolina.

Mr. Chairman.—I did not have the pleasure of hearing the paper that was read, nor much of the discussion upon it, but I had the pleasure of hearing the remarks of the gentleman who last spoke, and I was very much pleased, because I think there is a bacterio-mania in New York, and the remarks of the gentleman will, I presume, have some influence toward arresting it.

I have witnessed a few cases of ovariectomy, and apparently the most unpromising of cases; and particularly one of the most unpromising cases was supposed to be ovarian tumor, but turned out to be a fibroid. The physician (Dr. Hanneman, of Winchester) was afraid. There was considerable abdominal effusion, which was supposed to be an ovarian dropsy. When they opened the abdomen, it turned out to be nothing but an abdominal effusion and a fibroid of the uterus. The surgeon was rather taken aback, and hesitated for some time whether to proceed; but he concluded, having gone that far, to remove the fibroid, which he did, excising as near to the uterus as he could. He excised the fibroid near the uterus; the patient had a profuse hæmorrhage, and he was unable to apply a ligature. Now, what I wished to say was, that it was one of the most unpromising cases. There was no Listerism practiced at all. This was in a negro cabin—a negro woman. There was no ligation of the pedicle, no antiseptics; there were sponges dipped in Monsel's solution, and applied freely in the cavity of the abdomen, not knowing where it was going, but, of course, intending to go to the cut surface. The sutures were closed up, and the physician went the next day prepared to wash it out with a solution, a fountain syringe, drainage tubes, etc., but found the woman so well and the wound so well united that in two weeks she was up and attending to her duties. That was a fibroid of the uterus, excised without any antiseptics whatever, excised in a negro cabin. Of course, there was great cleanliness observed—cottons applied, cleanliness—but no antiseptic treatment whatever. I also witnessed two cases of ovariectomy by my distinguished friend, Dr. Darby, of New York, where no antiseptics were used, and both succeeded. In one of these cases he removed the uterus and ovaries with a number of fibroids, and there was no antiseptics practiced whatever. A month after the operation, the woman wished to know if she could have sexual connection. (Laughter.)

Dr. Sutton, in reply.

Mr. Chairman.—There are two assertions which I have made in my paper, against which no proof has been adduced. I will read them again: 1. "If there be a general surgeon in this country who can show a record of eighty-three recoveries in a hundred cases of ovariectomy, let him speak out, and challenge the truth of this (the preceding) assertion"; and, 2. "I challenge the production of a single operator outside of a private or special hospital, who can show better than eighty-two recoveries in one hundred cases."

Now, gentlemen, we know that European operators have ninety-eight, ninety-seven and ninety-three per cent. of recovery right along. In this country, the best statistics are, eighty-three per cent. by Holman, of Boston, and a little over eighty-two per cent. by Dr. Alexander Dunlap. Now, if these gentlemen get eighty-one and eighty-two per cent. as against ninety-eight and ninety-seven and ninety-three per cent. by foreign operators, what is the cause of the difference? What is the reason that there is a difference between the statistics of these men and the statistics of foreign operators? Is it because the foreign

operator is a better surgeon? I deny that. There are as good surgeons in America to-day as ever carved with the knife in Great Britain or upon the continent of Europe. (Applause.)

But it is not the man who can do ovariectomy skillfully, but it is the man who can make his patient get well after ovariectomy; not the man who can cut, but the man who can cut and save his patient. (Applause.)

They tell us that precautions are not necessary. Is it worth while to stop for a moment to consider what the results have been in a few operations? Is it necessary to stop to consider when Dr. Quimby says he has performed six or seven cases with fifty per cent. of deaths? He does not consider that antiseptics are necessary; he will go from small-pox to a woman in labor. Is it a wonder that he has statistics showing fifty per cent. of mortality in ovariectomy? (Applause.)

Let me say to you that every man can decide his work by his own conscience. If he chooses to do an ovariectomy in the amphitheatre, in the presence of one hundred medical students, with dust flying about, with their clothes filled with the zymotic influences of the dissecting room, I say that, if that woman gets well in spite of all that, the Almighty is to be given more credit than the operator. (Laughter and applause.)

Now, gentlemen, again I put the proposition before you. European physicians succeed in America's own operation. What is the reason? The reason is in the direction I have pointed out. Let the wise follow, and let those who will, take the other course—it is nought to me! (Applause.)

Dr. Quimby: I wish to correct a statement made by Dr. Sutton. I did not say that antiseptic precautions were not necessary. The gentleman misunderstood me. Of course they are necessary, but not strained to the point that gentlemen have sought.

Dr. Seymour, of Troy, New York.

Mr. Chairman.—I wish to correct a statement Dr. Sutton has made in regard to Dr. Holman. Dr. Holman has eighty-seven per cent. The first five cases were fatal. Those were without antiseptics, and the next one hundred, under strict antiseptics, of which eighty-seven recovered. Dr. Holman is a general surgeon attached as surgeon to the Massachusetts General Hospital.

Dr. Hurd: What are Dr. Sutton's own statistics?

Dr. Sutton: Dr. Holman, in his published tabulated statement, gives a large proportion of his cases as done at No. 14 Lewisburg Square, Boston. Is that a private hospital?

Dr. Seymour: It is in a measure so.

Dr. Sutton: I assert that Dr. Holman proceeds under the precautions of my paper, and that he has a private hospital or special hospital facilities; that he is not a general surgeon, doing general surgery hither and thither. Am I not right, Dr. Marcy?

Dr. Marcy: Yes, sir.

Dr. Sutton: Now, Dr. Hurd wants to know my own statistics. I began doing ovariectomy in 1875, and from 1875 up to a little over three years ago, I had done but seven cases. Out of those seven cases that I did I had but four recoveries; out of my first three cases I had two recoveries. Now, my operations up to that date were

done just wherever I could get the patient, and make the best arrangements, and those arrangements were carried out always to the utmost extent possible under the circumstances.

Then, dissatisfied with my own results, and having an interest in this matter, I went abroad and watched the work for 19 months of the best operators in the world, and I saw plenty of them. I began my operations again wherever I could get the patients; and I "got left" right along every time, and had four deaths in succession. Last September I saw the folly of the course I was pursuing. It was not the patient, but the patient could not be surrounded with proper precautions in the houses about town. I opened a private hospital for this work exclusively, and in that house I have made abdominal sections seven times. Every one of those seven cases have recovered, and the highest temperature found in any one of them was $101\frac{1}{2}$. (Applause.) There was one supra-vaginal hysterectomy for deformed uterus, one supra-vaginal hysterectomy for fibroid tumors, one double ovariectomy for cystic tumors, and a supra-vaginal hysterectomy on the same patient. Now, in these seven cases—desperate cases, too—who got well, and who got well without causing me the loss of a single night's sleep, if they all got well in a private hospital, there is more in it than simply the manner in which the operation was done. Where you have the patient in her house, her husband will see her, her sister will see her, the children will come in; but when you put the patient under the restrictions of a private hospital, where the head of that hospital puts down his foot and lays down the law, the patient will get well, and the time will come when we will proceed in all cases as Holman is doing in Boston.

MEDICAL PROGRESS.

MATERIA MEDICA AND THERAPEUTICS.

A SEA ATMOSPHERE FOR THE SICK-ROOM.—Dr. B. W. Richardson, in the *Asclepiad*, gives a solution of peroxide of hydrogen (10 volumes strength) containing 1 per cent. of ozonic ether, iodine to saturation, and 2.50 per cent. of sea salt. The solution placed in a steam or hand-spray diffuser can be distributed in the finest spray in the sick-room, at the rate of 2 fluid ounces in a quarter of an hour. It communicates a pleasant sea odor, and is the best purifier of the air of the sick-room he has ever used. It is a powerful disinfectant as well as deodorizer, acting briskly on ozonized test solutions and papers.

ANATOMY AND PHYSIOLOGY.

ON THE PHYSIOLOGICAL EFFECT OF EXTIRPATION OF THE THYROID.—We have in the *Archiv für exp. Path.* a report from Schiff and a series of experiments on this subject, which is well condensed in the *Edinburgh Clinical Journal*. Schiff found some years ago (1856) that the majority of animals operated upon for extirpation of this gland, passed, some days

or a week or two after the operation, into a peculiar soporific state and died. To explain this, Schiff performed these subsequent experiments, which went to show the following:

(1.) The mere laying bare of the thyroid gland, the section of the recurrent nerve in its neighborhood, the removal of nerve-branches passing to the gland from the recurrent nerve, did, none of them, occasion the peculiar symptoms which followed removal of the gland itself.

(2.) It was also found that the nerve-branches, which in the dog accompany the chief arteries of the gland, and which are branches of the superior laryngeal nerve, might be cut without producing these peculiar symptoms.

Length of survival after operation.—All the animals died without exception, surviving from four to twenty-seven days, and in those which passed the sixteenth day the operation wound was fully healed.

General phenomena.—Occasionally Schiff observed no other symptoms than those which he had already noted in former experiments, viz.: somnolence, loss of appetite, difficulty of swallowing, staggering gait, coma, and death. In other cases he observed that the ordinary condition of the animal was changed, that it was no longer excited when any one approached its cage, but was apathetic. The sleep which showed itself in most of the dogs showed this characteristic, that the animals could not be awakened by noise, but at once awoke when they were touched or shaken.

Movements.—Besides the general slowness of the muscular movements, there was in almost every case well-marked fibrillary muscular contraction under the skin. At later periods these muscular contractions became more severe, and caused convulsive movements of the limbs. In one or two instances the symptoms amounted to tetanus. Schiff frequently observed increased irritability of the phrenic nerve. The normal rhythm of the costal respiration was maintained, but during inspiration and expiration each cardiac contraction produced a sudden contraction of the diaphragm. The process of deglutition was much interfered with.

Sensibility.—There was a feeling of tickling over the skin in many of the animals. The general sensibility of the skin of the limbs became gradually lost from the periphery towards the centre.

Vaso-motor system.—Very low blood-pressures were met with towards the end in several of the animals experimented upon. In two instances there was some cedema, which Schiff ascribes to irritation of vaso-dilator nerves, and which he says was similar to what is sometimes observed after long-continued stimulation of the cut sciatic nerve.

Regarding the whole question of the extirpation of the thyroid, Schiff remarks that the hypothesis naturally occurs to one that that gland has an intimate connection with the nutrition of the central nervous system. This question he proposes to consider more fully in a future communication.

VIVISECTION.—During the year 1883, according to the annual report just issued to Parliament (*The Med-*

ical Press), 569 experiments were performed on living animals in the United Kingdom of Great Britain, 34 of these being carried out in Ireland. Fifty-five experiments were performed without anæsthetics, and 122 under certificates giving permission to preserve the life of the animal after recovery from anæsthesia. Concerning this last class of experiments, the report states that in 114 cases the operation consisted of inoculation with various septic matters or morbid organisms, for the greater part connected with an important inquiry into the nature of tubercular affections. No pain was inflicted in these cases, except in about fourteen or fifteen instances, in which disease was produced, but which was very trifling. In the remaining eight cases, in which more serious operations were required, as these were effected under anæsthesia, the only suffering in the animals that survived would be that which attends the ordinary repair of a "surgical injury."

MEDICINE.

ON A PARTICULAR FORM OF AMNESIA. LOSS OF NOUNS.—Dr. W. H. Broadbent presented a paper on this subject before the Royal Medical and Chirurgical Society of London (Proceedings). The patient was a gentleman, aged 77 at death. He had a slight and fugitive attack of right hemiplegia, with predominant affection of the face and hemianæsthesia, and an affection of speech, which in about a month settled down to the defect characterized by the impossibility of saying nouns substantive, while other parts of speech were spoken freely and distinctively, which remained the same for more than five years. During all this time he never uttered a noun, except once or twice by accident, so to speak, and inappropriately, while he could say other words and employ long phrases so long as they did not contain a noun. When he wished for anything he would say "Please give me the one," and the nurse would make guesses what it was. Other mental functions normal.

The lesions found after death were limited to the left hemisphere of the brain, and consisted of small and unimportant depressions in the posterior part of the intra-ventricular corpus striatum, slight diminution in size of the thalamus, complete atrophy of the calcaravis in the posterior cornu of the ventricle, and, finally, an extensive area of softening within the fissure of Sylvius in the posterior half of its extent, sparing altogether the anterior and antero-lateral convolutions of the insula, the third frontal, and the foot of the two convolutions of Rolando, destroying completely the two long posterior convolutions of the island and the subjacent white fibres down to and including the corresponding part of the external capsule, but not invading the lenticular nucleus (or extra-ventricular corpus striatum), and undermining the supra-marginal lobule and angular gyrus, but not implicating the entire thickness of their axial white fibres or reaching the convexity of the hemisphere. The infra-marginal or first temporo-sphenoidal convolution was remarkably little affected.

The hypothetical mechanism of speech and thought advanced by the writer, assumes that in the highest

or cerebral, as in the lowest or spinal nerve-centres there are sensory and motor departments, the motor apparatus being educated, so to speak, by the sensory; this education being represented structurally by the formation of groups of cells, through which orderly movements are effected.

On the sensory side, it is supposed that in the integration of speech and thought, perceptions from the different perception centres converge upon a common cortical area where they are combined or elaborated into an idea, this idea being symbolized by the associate auditory perception or name. The corresponding motor-centre to this name or idea-centre is supposed to be a propositionizing centre, in which takes place the mental rehearsal of a phrase or sentence, which is a necessary antecedent to its utterance.

Hence if the path from the visual perception centre to the naming centre were interrupted, the sight of an object would no longer recall its name, and a case answering to this condition has been related to the Society. Again, damage to the tract of fibres passing from the auditory perception centre to the naming centre would prevent the patient from understanding what was said to him. The case forming the subject of this paper is supposed to illustrate damage to the communicating tract between the naming and the propositionizing centres. The patient could rehearse a phrase in his mind, but the name or noun was not supplied from the appropriate centre.

CURABILITY AND TREATMENT OF LOCOMOTOR ATAXY.—Among 300 cases which Eulenberg has been able to follow, he has found only three cures. He believes, however, that the number might be increased were sufficient energy expended on the treatment. He holds that the curative action of silver is incontestable, but that it is often inert when given in the form of pill or powder. He recommends that it should be given subcutaneously, either as the albuminate, or as the hyposulphite.

R Chloride of silver.....10 centigr.

Hyposulphite of sodium.....10 centigr.

Distilled water.....20 grammes. M

An injection is given daily in the dorsal region, of 10 centigrammes to 1 gramme. There is generally a temporary disappearance of the pains, and when they reappear after two or three hours they are generally removable by a cold compress. Hypodermic injections of strychnine in doses of 4 to 6 milligrammes have, in several cases, been followed by a remarkable diminution of the motor and sensory disorders. Local refrigeration by means of ice or cold compresses along the vertebral column has had beneficial results. The degree of cold has been determined by the individual sensibility of the patient. With the nitrate of silver, the continuous current, and local cooling, he has in numerous cases improved the patient's condition.

SKRLJERO.—The Vienna correspondent of the *Medical Times* gives a case of this unpronounceable disease with remarks by Prof. Neumann. It seems that in the spring of this year this curious disease formed

the subject of a discussion in the Austrian Parliament. The government proposed that thirty thousand florins (\$12,500), should be granted for the suppression of the disease, which was extremely prevalent in the maritime districts of Croatia and Dalmatia, and which, according to the opinion of the chief sanitary authorities and of the Professors Hebra and Sigmund, was nothing else than syphilis. Persons suffering from it were to be compelled to undergo regular treatment. Dr. Roser opposed the motion, and proposed that a committee of specialists should be appointed to again enquire into the character of "skrljero," and that the necessary measures should be taken after they had reported. Professor Schneider, the adviser of the ministers, took the side of the government, and referred to the opinions already pronounced by the authorities mentioned above, upon which the motion of Dr. Roser was thrown out, and the proposal of the government accepted.

The notes of the case state that the patient was a native of Dalmatia, aged 24, who four years previously had intercourse with a woman who suffered from skrljero, and that since that time he had suffered from a disease which began with an ulceration on the penis, and was followed at an interval of some weeks by ulcers and nodules on the skin, which appeared and disappeared. He also calls his disease skrljero. The patient now presents the following symptoms: On the upper and lower extremities are to be seen round and oval cicatrices varying in size, denuded of their pigment in the centre, but containing some pigment at their periphery. These cicatrices are especially marked on the extensor muscles of the extremities, in several places they run into each other and present a bilobate or trilobate outline. The forehead, the ridge of the nose, the zygomatic processes, and the upper jaw are covered with white cicatrices of the size of a lentil, the space between these cicatrices presenting several nodules. Similar cicatrices and nodules are also present on those parts of the head which are denuded of hair; the two alæ nasi are converted into thin cicatrices, and stand at a higher level than usual, so that the septum is quite uncovered. Taking all these symptoms into consideration it is evident that this affection is syphilitic disease in the tertiary stage, in fact tertiary syphilis.

This patient was not submitted to specific treatment during the four years that he has been diseased, and he has been in want of proper nourishment. If a disease of this kind is not treated in the proper manner, if, moreover, it is complicated with other diseases, there take place aberrations in the course of the syphilitic progress, giving rise to symptoms which deviate very often from those we are accustomed to see, and which we recognize as syphilis only with difficulty, and after long and careful examination. Hence names have been invented for different endemic forms of disease, as skrljero in the Fiume littoral, radesyge in Norway, fibbens in Scotland, morbus dittmarsicus in the marshy regions of Germany, falcadine in Italy, pian and yaws in Africa, all of which are believed to be endemic diseases with an independent existence. But if we examine the diseases which are called by such different names,

we find that they represent a series of chronic diseases, which are to be found also with us, and among which syphilis, lupus, scabies, psoriasis, and chronic skin-ulcerations are the most common and play the chief part. The syphilitic cases of skrljero are characterized by the fact that an anti-syphilitic treatment, especially a mercurial one, is followed by rapid cure.

SURGERY.

A CASE OF FRACTURE OF THE ODONTOID PROCESS OF THE AXIS.—Küster (*Centralblatt für Chirurgie*; *Edinburgh Clinical Jour.*) gives a case which is one of great surgical and forensic interest; the patient being a girl, æt. 18, whose occiput was repeatedly struck against a beam. Immediately after the injury, slight pain and stiffness were complained of, but she performed her usual duties during the remainder of the day. On the following day, on attempting to rise, she was suddenly attacked with convulsions, and became speechless. For five days there was no return of consciousness, and the power of speech returned only at the end of nine months.

Fourteen months after the injury was received, the case came under the care of Professor Küster. At that time there was motor paresis of the extremities, with a marked increase of reflex excitability, especially of the tendon reflex, and great tenderness of the cervical portion of the spinal column. There was also complete inability to hold up the head, with increased prominence of the spinous process of the axis, and abnormal prominence of that vertebra anteriorly at the posterior pharyngeal wall, immediately below the basis cranii.
